This is an Accepted Manuscript, which has been through the Royal Society of Chemistry peer review process and has been accepted for publication.

Accepted Manuscripts are published online shortly after acceptance, before technical editing, formatting and proof reading. Using this free service, authors can make their results available to the community, in citable form, before we publish the edited article. We will replace this Accepted Manuscript with the edited and formatted Advance Article as soon as it is available.

You can find more information about Accepted Manuscripts in the [author guidelines](#).

Please note that technical editing may introduce minor changes to the text and/or graphics, which may alter content. The journal's standard [Terms & Conditions](#) and the ethical guidelines, outlined in our [author and reviewer resource centre](#), still apply. In no event shall the Royal Society of Chemistry be held responsible for any errors or omissions in this Accepted Manuscript or any consequences arising from the use of any information it contains.

## Hg<sup>2+</sup> and Cd<sup>2+</sup> binding of a bioinspired hexapeptide with two cysteine units constructed as a minimalistic metal ion sensing fluorescent probe

Hg<sup>2+</sup> and Cd<sup>2+</sup> complexation of a short hexapeptide, Ac-DCSSCY-NH<sub>2</sub> (DY), was studied by pH-potentiometry, UV and NMR spectroscopies and fluorimetry in aqueous solutions and the Hg<sup>2+</sup>-binding ability of the ligand was also described in immobilized form, where the peptides were anchored to a hydrophilic resin. Hg<sup>2+</sup> was demonstrated to form a 1:1 complex with the ligand even at pH = 2.0 while Cd<sup>2+</sup> coordination by the peptide takes place only above pH ~ 3.5. Both metal ions form bis-ligand complexes by the coordination of four Cys-thiolates at ligand excess above pH ~ 5.5 (Cd<sup>2+</sup>) and 7.0 (Hg<sup>2+</sup>). Fluorescence studies demonstrated a Hg<sup>2+</sup> induced concentration-dependent quenching of the Tyr fluorescence until a 1:1 Hg<sup>2+</sup>:DY ratio. The fluorescence emission intensity decreases linearly with the increasing Hg<sup>2+</sup> concentration in a range of over two orders of magnitude. The fact that this occurs even in the presence of 1.0 eq. of Cd<sup>2+</sup> per ligand reflects a complete displacement of the latter metal ion by Hg<sup>2+</sup> from its peptide-bound form. The immobilized peptide was also shown to bind Hg<sup>2+</sup> very efficiently even from samples at pH = 2.0. However, the existence of lower affinity binding sites was also demonstrated by binding of more than 1.0 eq. of Hg<sup>2+</sup> per immobilized DY molecules under Hg<sup>2+</sup>-excess conditions. Experiments performed with a mixture of four metal ions, Hg<sup>2+</sup>, Cd<sup>2+</sup>, Zn<sup>2+</sup> and Ni<sup>2+</sup>, indicate that this molecular probe may potentially be used in Hg<sup>2+</sup>-sensing systems under acidic conditions for the measurement of μM range concentrations.

### Introduction

Hg<sup>2+</sup> and Cd<sup>2+</sup> ions can induce serious cytotoxic effects and cancer development in living organisms. Among others, Cd<sup>2+</sup> can interfere with DNA repair mechanisms and causes osteoporosis by mimicking Zn<sup>2+</sup> and Ca<sup>2+</sup> ions.<sup>1,2</sup> The high affinity of Hg<sup>2+</sup> to the sulfhydryl groups of thiols has long been accepted to play a role in Hg<sup>2+</sup> toxicity. Nevertheless, it has also been suggested that the major mechanism of toxicity is related to its interaction with the selenocysteine residues of glutathione peroxidase and thioredoxin reductase, leading to the inhibition of gap junction-mediated intercellular communication and proinflammatory cytokine production.<sup>3,4</sup> Cellular defence mechanisms remove these toxic metal ions from the cytosol. In many bacteria the removal of Cd<sup>2+</sup> ions, owing to their similarity to Zn<sup>2+</sup>, can be implemented by multication resistance-mediating CzcABC efflux pumps<sup>5</sup> and by the P-type ATPase ZntA or the more specific CadA systems.<sup>6</sup> In contrast, the detoxification of Hg<sup>2+</sup> takes place in the form of Hg<sup>0</sup> via the

specific mercury resistance *mer* system.<sup>7,8</sup> Cys-abundant sequence motifs can provide efficient Hg<sup>2+</sup> and Cd<sup>2+</sup> binding for proteins. The CXXC motif often constitutes the metal ion binding site in proteins, like in rubredoxins,<sup>9</sup> P-type ATPases,<sup>10</sup> alcohol dehydrogenases,<sup>11</sup> zinc fingers,<sup>12</sup> metallochaperones,<sup>13,14</sup> metallothioneins,<sup>15</sup> as well as in the members of the Hg<sup>2+</sup> and Cd<sup>2+</sup> selective resistance systems (MerP,<sup>16</sup> MerC,<sup>17</sup> CadA,<sup>6</sup> ZntA<sup>6</sup> NMerA<sup>18</sup>).

Hg<sup>2+</sup> can form extremely stable complexes with linear, {HgS<sub>2</sub>} type coordination mode with thiol ligands, e.g. Cys (logβ<sub>2</sub> = 39.4 – 43.6)<sup>19–21</sup>, BAL (logβ<sub>1</sub> = 44.8),<sup>22</sup> etc. The formation of this binding mode was observed during the interaction of Hg<sup>2+</sup> with many CXXC-type proteins, like MerP,<sup>16</sup> NMerA,<sup>23</sup> Atx1,<sup>24</sup> and with cyclic<sup>25,26</sup> or linear<sup>27,28</sup> metalloprotein model peptides, etc. The presence of amino acids with high rigidity and/or helical penalty (e.g. Pro, Gly) in the positions of X<sub>1</sub> and X<sub>2</sub> increases the Hg<sup>2+</sup> binding efficiency by preorganising the peptide structure. Moreover, the Hg<sup>2+</sup> complex of the rigid C<sub>D</sub>PPC peptide displays an exceptionally high stability constant (logβ = 40.0) even compared to the effective CPPC sequence.<sup>29</sup> There are also examples for the formation of bis complexes with a {HgS<sub>4</sub>} binding mode among proteins bearing a CXXC motif (HAH1,<sup>24</sup> Rubredoxins,<sup>30</sup> etc).

In its complexes, Cd<sup>2+</sup>, similarly to Zn<sup>2+</sup>, prefers to possess a tetrahedral coordination sphere with two or four thiolate moieties but Cd<sup>2+</sup> has a higher thiophilic character. When the coordination sphere of Cd<sup>2+</sup> is not saturated by thiolate groups,

the complexes are stabilized mostly by complementary binding of other functional groups. Interactions with the carboxylate groups of Glu and Asp units probably play a role in the selectivity of CadA and ZntA.<sup>31</sup> Besides monomeric bis complexes with a pure {CdS<sub>4</sub>} coordination mode, the presence of dimeric species with a mixed Cys-Glu ({CdS<sub>3</sub>O}) coordination was also observed in the system of Cd<sup>2+</sup> and a 71 amino acid long polypeptide, derived from CadA, at pH = 6.0.<sup>31</sup>

CXXC moieties are potentially applicable as metal ion binding units in Hg<sup>2+</sup> and Cd<sup>2+</sup> sensing systems, since their interaction is typically characterized by a well-defined stoichiometry, high efficiency and selectivity. Since these metal ions can accumulate in the food chain and therefore ingested by humans, they pose significant health risks, and therefore their fast, selective sensing and remediation is highly prioritised.<sup>8</sup> Sensing schemes for these metal ions, based on fluorimetry,<sup>32</sup> potentiometry,<sup>33–35</sup> impedance measurement,<sup>36</sup> protein-functionalized microcantilevers,<sup>37</sup> or differential surface plasmon resonance<sup>38</sup> etc., were already proposed. Peptide ionophores can be designed with an ability for signalling by introducing fluorescing residues or amino acids bearing fluorescing side chains into their sequence.<sup>39–41</sup> Metal ion binding to peptidic probes mostly induce fluorescence quenching, especially with Cu<sup>2+</sup><sup>42–53</sup> and Hg<sup>2+</sup>.<sup>42,48,54</sup> However, chelation can also enhance the fluorescence (CHEF) via electronic interactions between the fluorophore and the altered coordination sphere. This is very frequent with Zn<sup>2+</sup><sup>43,46–49,51,53</sup> and Cd<sup>2+</sup><sup>43,46–49</sup> but examples are also known with Ag<sup>+</sup>,<sup>42,46–48</sup> Pb<sup>2+</sup><sup>46,47</sup> and Hg<sup>2+</sup>.<sup>48</sup> In addition, the metal ion promoted conformational change of the peptide may lead to a “close contact” and thus to a Förster resonance energy transfer (FRET) effect between different fluorophore residues.<sup>46,50,52,54–56</sup> Aggregation induced emission (AIE) enhancement can also be utilized for the analysis of metal ions.<sup>57,58</sup> The response mechanism and the sensitivity and selectivity of a peptide sensor designed for a specific metal ion is highly influenced by the quality and quantity of the binding groups, as well as the fluorophores themselves, in addition to the amino acid sequence and the higher order peptide structure. Although many fluorescent peptides have already been tested as potential sensor candidates for Hg<sup>2+</sup>, Cd<sup>2+</sup> or other metal ions, examples where the studied ionophore bears a CXXC motif are rather scarce. In the unique case of the short Dansyl-CPGCW-NH<sub>2</sub> peptide, the intervening amino acids between the two Cys residues provide high backbone rigidity for the ionophore. Upon excitation of either of the two fluorophore units, Cd<sup>2+</sup> ions induced a significant enhancement in the light emission of dansyl. Rather interestingly, Hg<sup>2+</sup> and Zn<sup>2+</sup> were shown to have no effect on the fluorescent response of the molecule.<sup>56</sup> Another notable, previously studied dicysteinylic peptidic probe possesses a CXXHC binding motif combined with dansyl and Trp fluorophores. This probe displayed a ratiometric turn on response for Hg<sup>2+</sup>, Cd<sup>2+</sup>, Pb<sup>2+</sup>, Zn<sup>2+</sup>, and Ag<sup>+</sup> ions upon the excitation of either of the two fluorophore units.<sup>46</sup> In addition, Joshi and co-workers also observed a turn-on response for Zn<sup>2+</sup> with two fluorescent peptides containing a Cys and a His residue in a 1,4-arrangement.<sup>47,49</sup>

Optochemical sensors, constructed by the covalent attachment of fluorescent peptides to the surface of solid carriers (e.g. optical fibers) may allow in-situ trace analysis of toxic metal ions with low sample quantity requirements. Such systems may present simple alternatives to currently used reliable, but expensive and robust laboratory-based instrumental methods. Despite the fact that several studies have already reported the successful design of such sensors,<sup>32,59–61</sup> there have only been a very few attempts to characterize the metal capturing peptide elements both in their dissolved and immobilized forms.<sup>47,49</sup> With an aim of exploiting the metal ion binding properties of the CXXC motif, we designed and synthesized the short, DCSSCY hexapeptide in an acetylated and amidated free form (Ac-DCSSCY-NH<sub>2</sub> (DY)) and in an immobilized, resin-attached form (DY-NTG). Compared to other aromatic amino acids, Tyr is less hydrophobic and still exhibits a reasonable quantum yield (0.14).<sup>62</sup> The fluorescence of Tyr has proved to be applicable in determining the Cu<sup>2+</sup> complex stabilities of different peptides,<sup>63–65</sup> in spite of the relatively close excitation ( $\lambda_{EX} = 275$  nm) and emission ( $\lambda_{EM} = 304$  nm) maxima of the fluorophore.<sup>62</sup> Accordingly, this simple ligand and the obtained data may be relevant in the design of peptide-based metal ion sensing systems.

## Results and discussion

### UV absorption experiments

UV absorption spectra of DY, as a function of pH, were recorded in the absence and presence of metal ions with the purpose of monitoring the effect of Hg<sup>2+</sup> and Cd<sup>2+</sup> on the deprotonation processes of the ligand. As it is expected, the proton dissociation of both the Cys –SH groups and the phenolic –OH group markedly influence the recorded spectra, even in the absence of metal ions (Figure S1). Deprotonated thiol groups are characterized by a UV-band centred around  $\lambda = 235$ –236 nm<sup>66,67</sup> while the proton release from the Tyr–OH function is known to result in a shift of two characteristic absorption peaks from 223 to 240 nm and from 277 to 295 nm.<sup>68</sup> The dissociation of the Asp sidechain carboxyl group does not have a noticeable spectral influence in the  $\lambda = 220$  – 400 nm range. Since the Cys and Tyr residues all deprotonate above neutral pH, a continuous evolution of the absorbance is observed between pH ~ 6.5 and 11.0 around 240 nm while the absorbance at 295 nm starts increasing from a notably higher pH, above pH ~ 8.5 (Figure S1), indicating the exclusive effect of the deprotonation of the Tyr residue. One may estimate the pK<sub>a</sub> value of the Tyr –OH function from the A<sub>295nm</sub> vs. pH plot (Figure S1) to be around 10.0 which is in line with the data determined from pH-metric titrations (see later).

UV/pH titrations were conducted in the presence of 0.5 and 1.0 equivalent of Hg<sup>2+</sup> ions within the range of pH ~ 1.8 – 11.0 (Figure S2) and representative absorbance traces from selected wavelength values are depicted in Figure 1.A. The significantly larger absorbances observed at pH = 1.8 at  $\lambda \sim 210$  – 230 nm in the presence of Hg<sup>2+</sup> relative to the metal ion free sample is originated from S<sup>–</sup>–Hg<sup>2+</sup> charge transfer bands and clearly

indicate peptide binding to the metal ion, as was also observed previously for other systems of  $\text{Hg}^{2+}$  and cysteine containing peptides under acidic conditions.<sup>29,69–71</sup> Furthermore, the absorbance increase, induced by  $\text{Hg}^{2+}$ -binding, seems to be proportional to the applied  $\text{Hg}^{2+}$ :DY ratio (Figures 1.A and S2.B) between pH  $\sim 1.8 - 7.0$ . At the same time, absorbances in the higher wavelength regime, i.e. around 295 nm, are almost identical independently of the  $\text{Hg}^{2+}$  concentration. These findings suggest an unvarying speciation up to neutral pH at any  $\text{Hg}^{2+}$ :DY ratio (and even up to pH 11.0 at one equivalent of  $\text{Hg}^{2+}$  per peptide) and the high energy charge transfer band, characterized by an absorption maximum below 220 nm (see the calculated difference spectra in Figure S3.), indicates a  $\{\text{HgS}_2\}$  type coordination mode in the complexes formed.<sup>26,29,69,70,72,73</sup>

coordination sphere of  $\text{Hg}^{2+}$  above neutral pH, most probably induced by the coordination of a second ligand and the formation of additional  $\text{S}^- - \text{Hg}^{2+}$  bonds. LMCT bands with maxima around 240–250 nm or 280–300 nm in the UV spectra of  $\text{Hg}^{2+}$ -thiolate complexes were previously assigned as signatures of trigonal  $\{\text{HgS}_3\}$ <sup>74,75</sup> or (pseudo)tetrahedral  $\{\text{HgS}_4\}$  species, respectively,<sup>30,75,76</sup> and this suggests that the two DY ligands binds  $\text{Hg}^{2+}$  with both of their two thiolates under basic conditions (see Figure S3). The slight bathochromic shift of the absorption maximum, observed above pH  $\sim 9.5$  (Figure S2.A), is presumably the effect of the deprotonation of the Tyr residues of the bound ligands taking place without metal ion assistance. This interpretation is further supported by the fact that isosbestic points are observed above pH 10 at  $\lambda \sim 264$  nm and  $\sim 282$  nm (Figure S2.A), indicating a simple transition between two species.

The pH-dependent series of UV spectra recorded for  $\text{Cd}^{2+}$ :DY 0.5:1 and 1:1 (Figures 1.B and S4) indicate metal ion coordination via the formation of thiolate- $\text{Cd}^{2+}$  bonds from pH  $\sim 4.5$ . The  $A_{240\text{nm}}$  vs. pH profiles, representing the evolution of  $\text{S}^- - \text{Cd}^{2+}$  charge transfer bands,<sup>77–83</sup> suggests that metal ion binding is essentially complete by pH  $\sim 6$  at 1 eq. of  $\text{Cd}^{2+}$  per ligand, however, the curve for  $\text{Cd}^{2+}$ :DY 0.5:1 is characterized by a narrow plateau near pH 6 and a second step levelling off above pH  $\sim 7.5$  (Figure 1.B). This indicates a different complexation pathway when the peptide is in excess over  $\text{Cd}^{2+}$ . One may presume the formation of bis-ligand species, as was also reported for the  $\text{Cd}^{2+}$  binding of other short, two Cys-containing peptides.<sup>79–81,84</sup> This is also supported by the systematically higher absorbances observed for  $\text{Cd}^{2+}$ :DY 0.5 relative to those observed both for  $\text{Cd}^{2+}$ :DY 1:1 and for the free ligand (Figure 1.B). Indeed, the molar extinction coefficients for  $\lambda = 240$  nm that one may estimate for the species present at pH  $\sim 8.0$  at 0.5 and 1 eq. of  $\text{Cd}^{2+}$  per ligand ( $25\ 100\ \text{M}^{-1}\ \text{cm}^{-1}$  and  $11\ 700\ \text{M}^{-1}\ \text{cm}^{-1}$ ) correspond well to four and two thiolates coordinated  $\text{Cd}^{2+}$ -centres, respectively.<sup>77,78</sup> The further increase of absorbance above pH 8 (at any  $\text{Cd}^{2+}$ :DY ratio) is most likely the consequence of the deprotonation of the Tyr sidechain phenols, nevertheless, other processes that may affect the coordination sphere of the metal ion, e.g. proton release(s) from  $\text{Cd}^{2+}$ -coordinated water molecules, may also contribute to the observed spectral changes under alkaline conditions.

#### $^1\text{H}$ NMR studies

$^1\text{H}$  NMR spectra of the free peptide were recorded as a function of pH (Figure S6) and resonances of DY were assigned as described in the Experimental part and are shown in Figure S5. We performed NMR titrations in the  $\text{Hg}^{2+}$ :DY (Figure 2) and  $\text{Cd}^{2+}$ :DY (Figure S9) systems by changing the metal ion to ligand ratio at selected pH values or at constant  $\text{Hg}^{2+}$ :DY ratios (0.5:1 and 1:1) as a function of pH (Figures S7–S8). However, pH-dependent  $^1\text{H}$  NMR experiments were not executed for  $\text{Cd}^{2+}$ :DY because of severe line broadening and poorly resolved resonances observed for all of the signals already at 0.25 eq. of  $\text{Cd}^{2+}$  per ligand (see Figure S9). We had previously observed a similarly strong influence of  $\text{Cd}^{2+}$  on the  $^1\text{H}$  NMR signals of other,

Figure 1. Absorbances at selected wavelength values as a function of pH, recorded for  $\text{Hg}^{2+}$ :DY (A) and  $\text{Cd}^{2+}$ :DY (B). ( $c_{\text{DY}} = 1 \times 10^{-4}$  M (A) or  $5 \times 10^{-5}$  M (B),  $T = 298$  K).

A remarkable difference between the speciation in  $\text{Hg}^{2+}$ :DY 0.5:1 and 1:1 above pH  $\sim 7.5$  is reflected by the  $A$  vs. pH profiles at 295 nm. The absorbances observed for  $\text{Hg}^{2+}$ :DY 1:1 up to pH = 11.0 are nearly identical with those obtained for the free ligand suggesting that the bound  $\text{Hg}^{2+}$  has only a minor influence, if any, on the deprotonation of the Tyr sidechain group. The remarkably different  $A_{295\text{nm}}$  vs. pH trace of  $\text{Hg}^{2+}$ :DY 0.5:1 (Figure 1.A) suggests a fundamental rearrangement in the

relatively short, Cys-containing peptides<sup>81,85</sup> and as in those reported cases, the line broadening seen in the spectra of Cd<sup>2+</sup>:DY indicates ligand exchange and/or conformational dynamics occurring in an intermediate time regime, relative to the NMR time scale.

The deprotonation processes of the carboxyl group of the Asp residue, the two Cys-thiols and the sidechain phenolic function of Tyr in the free DY ligand can be clearly followed by the gradual shifting of the corresponding C<sub>β</sub>H<sub>2</sub> resonances or the C<sub>β</sub>H and C<sub>γ</sub>H signals of Tyr towards lower chemical shifts in the relevant pH-ranges (Figure S6). The presence of Hg<sup>2+</sup> has only minor effect on the shape and chemical shift of these resonances (with the exception of the slightly more influenced C<sub>β</sub>H<sub>2</sub> signals of Asp – see later), suggesting that Hg<sup>2+</sup> does not bind to these moieties. As opposed to this, below neutral pH Hg<sup>2+</sup> binding of the two thiolates are represented by the collapse of the Cys C<sub>β</sub>H<sub>2</sub> signals of the unbound ligand and the emerging new resonances attributed to the bound molecule (see the effect of the increasing Hg<sup>2+</sup>:DY ratio at pH = 5.7, Figure 2.A). This indicates that the ligand exchange dynamics is moderately slow at this pH, relative to the NMR timescale.

Figure 2. <sup>1</sup>H NMR spectra of DY obtained with varying equivalents of Hg<sup>2+</sup> per peptide at pH = 5.7 (A) and 8.5 (B) (H<sub>2</sub>O:D<sub>2</sub>O = 90:10 % v/v, c<sub>DY</sub> = 1.0 × 10<sup>-3</sup> M, T = 298 K). The symbol '\*' denotes <sup>1</sup>H resonances of the ligand in its metal bound state.

The pH-dependence of resonances observed with 0.5 eq. of Hg<sup>2+</sup> per peptide agrees excellently with the UV data and with

the formation of a bis-ligand complex with a {HgS<sub>4</sub>} coordination geometry. The fact that the chemical shifts of the Cys protons lie in between those of the free peptide and the resonances of the mono-complex (see the broad peaks around 2.9 and 3.2 ppm on the middle spectrum in Figure 2.B) may simply reflect that Hg<sup>2+</sup> quite efficiently attracts electrons in the {HgS<sub>2</sub>} type species, but that this effect (per cysteine) is less pronounced in the {HgS<sub>4</sub>} structure. Consequently, the deshielding effect on the Cys protons caused by Hg<sup>2+</sup> coordination is weaker for the {HgS<sub>4</sub>} than for {HgS<sub>2</sub>} structures. It is also interesting to note that the signals of the Cys C<sub>β</sub>H<sub>2</sub> protons are hardly observable around neutral pH at 0.5:1 Hg<sup>2+</sup>:DY ratio (Figure S7.A), possibly as a consequence of severe line broadening. This might imply that the increase of pH and approaching the range where the thiol groups of the unbound ligands deprotonate has an influence on the ligand exchange rate and that ligand exchange dynamics also affects the observed Cys C<sub>β</sub>H<sub>2</sub> resonances.

#### Complex speciation in the metal ion – peptide systems, unravelled by pH-potentiometric titrations

pH-potentiometry is, in general, a powerful method for the characterization of complex formation processes that lead to the release of protons from the metal ion binding moieties of the ligand, and pK<sub>a</sub> values of the free ligand and its Cd<sup>2+</sup> complexes are presented in Table 1. However, Hg<sup>2+</sup> ions are bound so efficiently to ligands with thiol groups, including the studied DY peptide, that the free metal ion fraction is negligible even at the very acidic end of the pH-range coverable by a glass electrode.<sup>29,69–71</sup> As a consequence, the relevant metal-ion induced deprotonation processes are completed at the initial pH of the titrations and thus the method is not directly applicable to the determination of stability constants in such systems. (An indirect pH-metric approach for the characterization of Hg<sup>2+</sup>-peptide complex speciation using a competing Hg<sup>2+</sup>-binding ligand has been previously reported by Iranzo *et al.*<sup>29</sup>). In spite of the limitations of this method for the present system, we executed pH-potentiometric titrations aiming to follow the various deprotonation processes occurring at the Hg<sup>2+</sup>-bound peptide(s) and to determine the proton dissociation constants characterizing the interconversion of the differently protonated complex species. These data, collected in Table S1 in the ESI, allowed of the calculation of species distribution curves for Hg<sup>2+</sup>:DY 0.5:1 and 1:1 (Figure 3) based on the plausible assumption that the species present at pH = 2.0 is HgH<sub>2</sub>L with two Hg<sup>2+</sup>-coordinated thiolate groups and protonated Asp and Tyr residues of the ligand. Indeed, the calculation of such a speciation scheme required the overall formation constant (logβ) of one of the species to be fixed (conveniently the logβ of HgH<sub>2</sub>L). Since we did not have an experimentally measured value for logβ<sub>HgH<sub>2</sub>L</sub> we assumed that the Hg<sup>2+</sup> + [H<sub>2</sub>L]<sup>2-</sup> ⇌ [HgH<sub>2</sub>L] process of DY could be characterized by the same stability constant as that of the parent mono complex (HgL) of the terminally protected CdPPC peptide, determined by Iranzo *et al.* (logK = 40.0).<sup>29</sup> By this assumption we could set a fixed, "arbitrary" logβ<sub>HgH<sub>2</sub>L</sub> value (see more details in the Supplementary information) required for

data evaluation. Note that it does not affect the conclusions of this work how closely this arbitrary stability data approaches its real value, as long as it is high enough to ensure a complete binding of  $\text{Hg}^{2+}$  at the lowest utilized pH. This is also reflected by model calculations where in spite of the different applied  $\log \beta_{\text{HgH}_2\text{L}}$  values the resulting  $\text{pK}_a$  data for the deprotonation processes of the complexes turned out to be identical (Table S2). The calculated distribution of species (Figure 3) well supports all of our previous conclusions drawn from the spectroscopic data. The  $\text{pK}_a$  values associated with the release of the two protons, leading to  $[\text{HgHL}]^-$  ( $\text{pK}_a = 4.1$ , Table S1) and then to  $[\text{HgL}]^{2-}$  ( $\text{pK}_a = 9.6$ , Table S1), are close to the values determined for the deprotonations of the Asp and Tyr units of the free ligand, respectively ( $\text{pK}_{a,1} = 3.80$  and  $\text{pK}_{a,4} = 10.05$ , see Table 1). This indicates that the deprotonation of these groups are essentially not affected by the metal ion in the  $\text{Hg}^{2+}$ -bound peptide. At  $\text{Hg}^{2+}:\text{DY} = 0.5:1$  the bis-ligand complexes dominate above pH 8. Considering the characteristic pH-range for the presence of the differently protonated bis complexes and the observed position of their  $\text{S}^- - \text{Hg}^{2+}$  charge transfer bands, it is straightforward to suggest three coordinating thiolate groups in  $[\text{HgH}_3\text{L}_2]^{3-}$  and thus a  $\{\text{HgS}_4\}$  coordination mode in  $[\text{HgH}_2\text{L}_2]^{4-}$ . Similar to the deprotonation step of the  $[\text{HgL}]^{2-}$  parent complex, the two  $\text{H}^+$ -dissociation processes of the  $[\text{HgH}_2\text{L}_2]^{4-}$  species, occurring in the alkaline pH range ( $\text{pK}_a = 10.0$  and  $11.2$  - Table S1), are assigned to the deprotonation of non-coordinating Tyr sidechains. Proposed schematic structures for the  $\text{Hg}^{2+}:\text{DY}$  complexes are collected in Scheme S1.

Figure 3. Distribution of species in the  $\text{Hg}^{2+}:\text{DY}$  0.5:1 (continuous lines) and 1:1 (dashed lines) systems ( $c_{\text{DY}} = 1.0 \times 10^{-3} \text{ M}$ ,  $T = 298 \text{ K}$ ).

Evaluation of pH-potentiometric data obtained for  $\text{Cd}^{2+}:\text{DY}$  reveal that  $\text{Cd}^{2+}$ -binding occurs above  $\text{pH} \sim 3.5$  and the first dominant species, formed in parallel with a small amount of a dinuclear species, is a mono-protonated mono complex independently of the metal ion to ligand ratio (Figure 4).

The composition  $[\text{CdHL}]^-$  corresponds well with the coordination of both thiolates to  $\text{Cd}^{2+}$  and with a protonated Tyr phenol group in this species. Obviously, the Asp carboxyl function is deprotonated in  $[\text{CdHL}]^-$ , however, since the formation of this complex spans the pH-range where the Asp sidechain of the free ligand also deprotonates, pH-metric data

are not conclusive with regard to the  $\text{Cd}^{2+}$ -binding of this group. Previous studies on short oligopeptides containing both Cys and Asp residues reflected, however, that participation of the available carboxylate groups in  $\text{Cd}^{2+}$ -binding is possible,<sup>80,81,83</sup> even if two thiolate donors are also coordinated.<sup>80,81</sup> Binding of the Asp sidechain of DY to  $\text{Cd}^{2+}$  is supported by the stability constant calculated for the  $\text{Cd}^{2+} + [\text{HL}]^{3-} = [\text{CdHL}]^-$  process ( $\log K_1^{\text{H}} = 12.56$ ). This value is nearly identical to the stability that may be calculated for the relevant,  $\{\text{CdS}_2\text{O}_2\}$  type complex of a short phytochelatin peptide ( $(\gamma\text{-Glu-Cys})_2\text{-Gly-PC2}$ ,  $\log K_1^{\text{H}} = 12.57$ )<sup>80</sup> and significantly higher than the stability of the protonated mono complex of ACSSACS- $\text{NH}_2$  with only two coordinating thiolate groups ( $\log K_1^{\text{H}} = 10.22$ ).<sup>84</sup> The remarkable extra stability observed for the mono complex of DY is presumably only partly related to the additional binding of the Asp carboxylate group, and may also be a consequence of the more favoured CXXC amino acid pattern vs. the CXXXC sequence in the ACSSACS- $\text{NH}_2$  heptapeptide.

Figure 4. Distribution of species in the  $\text{Cd}^{2+}:\text{DY}$  0.5:1 (A) and 1:1 (B) systems ( $c_{\text{DY}} = 1.0 \times 10^{-3} \text{ M}$ ,  $T = 298 \text{ K}$ ).

Furthermore, the additional coordination of one of the internal peptide carbonyl groups, as suggested for PC2, is also possible in the  $[\text{CdHL}]^-$  complex of DY resulting in a  $\{\text{S}^-, \text{S}^-, \text{COO}^-, \text{CO}\}$  donor group environment around the metal ion. The  $\text{pK}_a$  value determined for the  $[\text{CdHL}]^- = [\text{CdL}]^{2-} + \text{H}^+$  process ( $\text{pK}_a = 9.83$ ) is very close to the  $\text{pK}_a$  of the Tyr residue in the free ligand indicating that the sidechain phenolate is not bound to  $\text{Cd}^{2+}$ ,

similarly to what was concluded for the Hg<sup>2+</sup> complexes of DY. (Suggested schematic structures for the Cd<sup>2+</sup>:DY complexes are shown in Scheme S2.) Calculation of the apparent dissociation constant for the Cd<sup>2+</sup>:DY mono complexes at pH = 7.0, according to the equation  $K_d = [\text{Cd}^{2+}]_{\text{free}} \times [\text{Ligand}]_{\text{free}} / [\text{Cd}^{2+}]_{\text{complexed}}$ , may allow to compare the Cd<sup>2+</sup>-binding affinity of DY to other relevant cysteine containing peptides or proteins. The calculated  $K_d = 9.1 \times 10^{-10}$  M value indicates a slightly larger Cd<sup>2+</sup>-binding affinity of DY compared to that of the PC2 phytochelatin peptide ( $K_d = 1.7 \times 10^{-9}$  M)<sup>80</sup> but a substantially stronger Cd<sup>2+</sup>-binding relative to the reduced glutathione ( $K_d = 1.4 \times 10^{-5}$  M).<sup>86</sup> However, the average dissociation constants determined for the  $\alpha$  and  $\beta$  domains of MT-2 metallothioneins ( $K_d = 1.0 \times 10^{-15}$  M ( $\alpha$ ) and 0.1–1.0  $\times 10^{-12}$  M ( $\beta$ ))<sup>87</sup> clearly reflect a more efficient Cd<sup>2+</sup>-coordination by these proteins, provided by the thiolate-clusters.

At twofold DY excess over Cd<sup>2+</sup> the bis-ligand complexes start to form from ca. pH 5 and become fully dominant by pH ~ 8 (Figure 4.A), as also suggested by the pH dependent evolution of the S<sup>-</sup>-Cd<sup>2+</sup> charge transfer band and the calculated molar extinction coefficient for  $\lambda = 240$  nm at Cd<sup>2+</sup>:DY 0.5:1, vide supra. The two proton release processes, leading from the four-thiolate coordinated [CdH<sub>2</sub>L<sub>2</sub>]<sup>4-</sup> complex to [CdHL<sub>2</sub>]<sup>5-</sup> and then to [CdL<sub>2</sub>]<sup>6-</sup>, are assigned to dissociations of the non-coordinating Tyr phenol sidechains (see Table 1). The stability constant calculated for the protonated bis complex ([CdHL]<sup>-</sup> + [HL]<sup>3-</sup> = [CdH<sub>2</sub>L<sub>2</sub>]<sup>4-</sup>,  $\log K_2^{\text{CdH}_2\text{L}_2} = 8.21$ ) and the relative stability of the protonated mono and bis-ligand species ( $\log(K_1^{\text{H}}/K_2^{\text{+2H}}) = 4.35$ ) indicate that binding of the second ligand is substantially less favoured than that of the first one. Very similar data have been reported for the bis complex formation of the phytochelatin pentapeptide PC2 ( $\log(K_1^{\text{H}}/K_2^{\text{+2H}}) = 4.39$ )<sup>80</sup> leading to a four thiolate coordinated species. The relative positions of the two Cys residues in DY and PC2 are different (CXXC, CXC) just as the overall charges of their relevant mono and bis complexes (DY: -1/-4, PC2: -2/-6), nevertheless, the two peptides are of similar sizes. This suggests that the relative binding strength of the second DY or PC2 ligand is determined by similar factors, i.e. the notably high stability of their mono complex and steric hindrance (bulkiness of the peptides) but the  $\log(K_1^{\text{H}}/K_2^{\text{+2H}})$  values are probably not large enough to assume a major change in the coordination geometry of Cd<sup>2+</sup>.

Logarithmic protonation constants and formation constants ( $\log \beta$ ) of the Cd<sup>2+</sup> complexes of DY (with the estimated errors in parentheses, last digit together with some calculated data ( $I = 0.1$  M NaClO<sub>4</sub>,  $T = 298$  K))

### Influence of metal ions on the fluorescence of the ligand

The effect of the metal ions on the fluorescence of the Tyr residue, as a function of the metal ion to DY ratio, was monitored at selected pH values, applying excitation at  $\lambda = 278$  nm. Gradual addition of Cd<sup>2+</sup> ions to a solution of the peptide at pH = 7.1 (Figure S10) showed a partial quenching (~35 % drop) of the original emission intensities, levelling off at a ca. 0.6-0.7:1 Cd<sup>2+</sup>:DY ratio. This  $I_{308\text{nm}}$  vs. Cd<sup>2+</sup>:DY ratio profile perfectly correlates with the disappearance of the free ligand, occurring slightly above a 0.5:1 Cd<sup>2+</sup>:peptide ratio at pH = 7.1 (see Figure 4.A), especially under the small concentrations used for the fluorimetric studies. Since further increase of the Cd<sup>2+</sup>:DY ratio was found to have no influence on the observed emission intensity, Cd<sup>2+</sup> seems to exert very similar quenching effect on the fluorescence of the Tyr residue, independently of the number of coordinated DY molecules. In a double (Trp and Dansyl) labelled peptide containing two Cys residues, Cd<sup>2+</sup> was found to induce a turn-on response, nevertheless, the chelation enhanced fluorescence also reached a maximum around a 0.5:1 Cd<sup>2+</sup>:peptide ratio, and accordingly, it was attributed to the presence of a bis complex.<sup>56</sup>

For the experiments in the Hg<sup>2+</sup>:DY system pH = 6.0 was chosen to apply a close-to-neutral condition while avoiding the occurrence of bis complexes and thus maintaining a relatively simple speciation that should be desirable for a molecular probe. In view of the outstanding affinity of DY towards Hg<sup>2+</sup> that, in contrast to Cd<sup>2+</sup>, results in a complete binding of this metal ion even at rather low pH values, we recorded Hg<sup>2+</sup>:DY ratio dependent emission spectra at pH = 2.0, as well.

Figure 5. Fluorescence titration of DY by  $\text{Hg}^{2+}$  at pH = 2.0 (circles) and pH = 6.0 (triangles) in the absence (filled symbols) and presence (open symbols) of  $\text{Cd}^{2+}$  ions. Fitted lines represent the trends in the decrease of intensity and the breakpoint at 1.0 eq. of  $\text{Hg}^{2+}$  ( $c_{\text{DY}} = 3.0 \times 10^{-5}$  M,  $\lambda_{\text{EM}} = 308$  nm,  $\lambda_{\text{EX}} = 278$  nm). The inset shows the recorded spectra at pH = 6.0 in the absence of  $\text{Cd}^{2+}$  ions.

As Figure 5 clearly shows, the increase of the concentration of  $\text{Hg}^{2+}$  leads to a significant drop of emission intensities, following a linear trend until reaching a 1:1  $\text{Hg}^{2+}$ :DY ratio both at pH = 6.0 and 2.0. This correlates well with the calculated complex speciation (Figure 3) and indicates a strong and complete binding of 1 eq.  $\text{Hg}^{2+}$  per DY. However, it also suggests that the ligand cannot capture a second  $\text{Hg}^{2+}$  ion in solution, which is also a desirable property for a  $\text{Hg}^{2+}$  sensor. Although different species dominate at the two selected pH values ( $\text{HgH}_2\text{L}$  at pH = 2.0 and  $[\text{HgHL}]^-$  at pH = 6.0), the observed trends in the decreasing fluorescence emission intensities are nearly identical in the two cases. This suggests that the protonation state of the uncoordinated Asp carboxyl group has no impact on the  $\text{Hg}^{2+}$ -induced quenching of the Tyr fluorescence.

Different possibilities may be considered for the mechanism of the metal ion induced quenching of the fluorescence of DY, as suggested by Chen's in-depth overview of the interaction of  $\text{Hg}^{2+}$  with proteins containing aromatic amino acids.<sup>88</sup> Indeed,  $\text{Hg}^{2+}$  was shown to quench the fluorescence of the vast majority of tested proteins, especially of those that contained Cys residues near the aromatic amino acids.<sup>88</sup> Although direct interaction of both of the studied metal ions with the Tyr residue of DY has been excluded in our systems, an overlap between the thiolate-related absorption bands and the Tyr emission might cause quenching via energy transfer. Besides, metal ion promoted conformational changes in the peptide structure may also play a role in the altered fluorescence.

We also tested the  $\text{Hg}^{2+}$ -induced quenching of the fluorescence of DY in the presence of 1.0 eq. of  $\text{Cd}^{2+}$ . Since the latter metal ion is not bound to the peptide at pH = 2.0 (Figure 4) it has no influence on the emission intensities at any  $\text{Hg}^{2+}$ :DY ratio. Nevertheless, 1.0 eq.  $\text{Cd}^{2+}$  per DY at pH = 6.0 induces a notable fluorescence quenching, as compared to the  $\text{Cd}^{2+}$ -free sample, reflecting that  $\text{Cd}^{2+}$ -DY complexes are present at the start of the titration. When this sample is titrated by  $\text{Hg}^{2+}$  the observed fluorescence is gradually quenched down to the same level as

seen in the absence of  $\text{Cd}^{2+}$ , suggesting that the DY-bound  $\text{Cd}^{2+}$  is completely displaced by  $\text{Hg}^{2+}$ .

DOI: 10.1039/C9DT01141B

In view of the potential analytical applicability of such a molecular probe the most promising findings of the above experiments are the significant fluorescence response of the ligand, proportional to  $\text{Hg}^{2+}$ -concentration up to a 1:1  $\text{Hg}^{2+}$ :DY ratio, as well as the remarkable metal ion binding selectivity that is also manifested in the  $\text{Hg}^{2+}$ -mediated changes in emission intensities. In this context, the data series recorded at pH 2 (Figure 5) demonstrates selective binding of  $\text{Hg}^{2+}$  at low pH, which may be used to eliminate interferences from other metal ions, such as  $\text{Cd}^{2+}$ , in a fluorophore based  $\text{Hg}^{2+}$  assay. A quick assessment of the potential analytical figures of merit for  $\text{Hg}^{2+}$  sensing under our measurement conditions yields an estimated limit of detection of ca.  $2 \times 10^{-7}$  M and a linear dynamic range exceeding 2 orders of magnitude.

### $\text{Hg}^{2+}$ binding of the DY peptide immobilized to a resin

Next we aimed to explore  $\text{Hg}^{2+}$  binding to the DY ligand in an immobilized form. To achieve this, we synthesized a construct carrying the peptide anchored to a hydrophilic resin (DY-NTG).  $\text{Hg}^{2+}$  binding to DY-NTG was studied as a function of contact time, pH and metal ion concentration at pH = 2.0. As a reference system, the peptide-free resin with acetylated terminal amino groups (Ac-NTG) was also tested at pH = 2.0 by adding 1.5 eq. of  $\text{Hg}^{2+}$  per the available blocked peptide anchoring sites. The determined 0.0354 mmole  $\text{Hg}^{2+}$  per g Ac-NTG metal ion binding capacity represents ca. 13% of the theoretical loading of the resin (quantity of available functionalization sites on the resin beads,  $L = 0.267$  mmole/g). It seems that a small but non-negligible amount of  $\text{Hg}^{2+}$  may be bound by Ac-NTG, probably at the polyethylene-glycol chains. However, such binding sites in the peptide functionalized resin, DY-NTG, may play a role in metal ion binding only under metal ion excess conditions.

Since metal ion complexation processes could be slower at the resin beads-supported binding sites as compared to the solution phase, first we determined the contact time necessary for a complete equilibration in the reaction of  $\text{Hg}^{2+}$  and DY-NTG. Samples were prepared at pH = 2.0 by adding  $\text{Hg}^{2+}$  ions in concentrations corresponding to 1.5, 2.0 and 3.0 eq. of  $\text{Hg}^{2+}$  relative to the theoretical loading of the resin, i.e. to the available immobilized peptide chains (0.227 mmole/g, see the sample preparation protocol in the Methods section). The excess of metal ion ensured that the concentration of  $\text{Hg}^{2+}$  could be conveniently and accurately measured back by ICP-MS after the termination of reaction. The studied samples were shaken for 30, 45, 60, 120, 180 and 300 minutes. Three additional samples, prepared with 0.33, 0.66 and 1.0 eq. of  $\text{Hg}^{2+}$  per peptide, were also tested by using 60 and 120 min contact times. Analysis of the remaining  $\text{Hg}^{2+}$  concentrations in all these samples showed that up to 1.0 eq. of  $\text{Hg}^{2+}$  per ligand the concentration of the metal ion was stable after 60 min (or even less, as suggested by other preliminary tests), however, 120 min equilibration time seemed to be necessary for samples containing metal ion excess. Accordingly, a contact time of 120

min was used for all further experiments, including those performed with the reference compound, Ac-NTG.

Figure 6.  $\text{Hg}^{2+}$  binding ( $\mu\text{mol}$ ) to the immobilized ligand at  $\text{pH} = 2.0$  plotted as a function of the original  $\text{Hg}^{2+}$  content ( $\mu\text{mol}$ ) of samples ( $V_{\text{sample}} = 10.0 \text{ mL}$ ;  $m_{\text{DY-NTG}} = 10.0 \text{ mg}$ ). The dashed line is a linear fit of data up to 1.0 eq. of added  $\text{Hg}^{2+}$  relative to the theoretical  $\text{Hg}^{2+}$  binding capacity of DY-NTG ( $L = 2.27 \mu\text{mol}/10 \text{ mg}$ ). The intercept of the narrow dotted lines represents an expected data point if 1.0 eq. of added  $\text{Hg}^{2+}$  is fully captured.

The effect of  $\text{pH}$  on the  $\text{Hg}^{2+}$  binding ability of DY-NTG was monitored between  $\text{pH} = 1.0$  and  $6.0$  by preparing samples of  $\sim 1.0$  eq.  $\text{Hg}^{2+}$  per DY ligand. In a good correlation with the complex speciation determined for the  $\text{Hg}^{2+}$ :DY system in solution (Figure 3), no variation in the bound metal ion quantity was observed. Consequently, the immobilized peptide resembles well the  $\text{Hg}^{2+}$  binding ability of DY in solution up to a 1:1  $\text{Hg}^{2+}$ :DY ratio, as indicated by the binding of ca. 95 % of the added  $\text{Hg}^{2+}$  ions to DY-NTG independently of the applied  $\text{pH}$  (Figure S11).

$\text{Hg}^{2+}$  binding to DY-NTG was investigated at  $\text{pH} = 2.0$  as a function of  $\text{Hg}^{2+}$  concentration in a range of  $0.774 - 6.49 \mu\text{mol}/10.0 \text{ mL}$  sample representing ca.  $0.34 - 2.86$  eq. of metal ion per available immobilized peptide (Figure 6). The bound quantity of  $\text{Hg}^{2+}$ , calculated from the remaining metal ion concentrations of the samples contacted with DY-NTG, increases linearly up to ca. 1.0 eq.  $\text{Hg}^{2+}$  per peptide. At this specific point the bound quantity of  $\text{Hg}^{2+}$ , as measured by ICP-MS, indicates that nearly 95 % ( $2.07 \mu\text{mole}$ ) of the added  $\text{Hg}^{2+}$  ions ( $2.20 \mu\text{mole}$ ) are bound. As seen in Figure 6, the bound  $\text{Hg}^{2+}$  quantity further increases in parallel with the increasing  $\text{Hg}^{2+}$  concentration of the samples and the obtained curve follows a saturation-like trend converging towards what appears to be  $\sim 2.0$  eq. bound  $\text{Hg}^{2+}$  per peptide. This suggests that other, weaker binding sites also participate in metal ion binding and the quantity of  $\text{Hg}^{2+}$  ions, captured at these sites, cannot be explained by the metal ion binding ability of the non-peptidic parts of the resin, considering the value measured for the reference Ac-NTG ( $0.0354 \text{ mmole/g}$ ). In some of the previously published studies on the metal ion binding abilities of cysteine containing peptides,<sup>89–91</sup> immobilized to various matrices, the authors also reported about the presence of binding sites with different affinities in their constructs.<sup>91</sup> Since solution phase experiments with the DY peptide showed that it was able to bind only one  $\text{Hg}^{2+}$  ion per molecule, coordination of the second

metal ion must be attributed to binding positions originating from the immobilization of the ligands. These positions are probably less accessible than the primary binding positions and might require a slow structural change of the solid supported ligands, as suggested by the longer contact times needed for equilibration when metal ion excess is used.

These results demonstrate that DY-NTG efficiently binds  $\text{Hg}^{2+}$  even at low  $\text{pH}$  ( $\text{pH} = 2.0$ ) and the bound quantity linearly increases with the increasing metal ion concentration in samples where the  $\text{Hg}^{2+}$  content does not exceed the theoretical  $\text{Hg}^{2+}$ -binding capacity of the resin.

Figure 7. Binding of different  $\text{M}^{2+}$  ions to the immobilized ligand ( $\mu\text{mol}$ ) at  $\text{pH} = 6.0$  ( $C_{\text{MES}} = 0.02 \text{ M}$ ) from two sample solutions containing 1.0 eq. ( $2.27 \mu\text{mol}$ ) (A) or 2.0 eq. ( $4.54 \mu\text{mol}$ ) (B) of all the four metal ions relative to the theoretical  $\text{M}^{2+}$  binding capacity of DY-NTG. ( $V_{\text{sample}} = 10.0 \text{ mL}$ ;  $m_{\text{DY-NTG}} = 10.0 \text{ mg}$ )

In order to test whether DY-NTG displays a selectivity in the binding of  $\text{Hg}^{2+}$ , two types of samples containing the resin and four selected metal ions,  $\text{Hg}^{2+}$ ,  $\text{Cd}^{2+}$ ,  $\text{Zn}^{2+}$  and  $\text{Ni}^{2+}$ , were prepared. Since data for  $\text{Cd}^{2+}$ :DY showed that this metal ion cannot be bound by the ligand at  $\text{pH} = 2.0$ , which most probably also holds for  $\text{Zn}^{2+}$  or  $\text{Ni}^{2+}$ , the metal ion selectivity experiments were performed at  $\text{pH} 6.0$  by applying 1.0 or 2.0 equivalents of all the four metal ions, relative to the available immobilized peptide, in both types of samples. The results obtained reveal a dominance of  $\text{Hg}^{2+}$  in occupying the available binding sites of DY-NTG, especially at twofold excess of the metal ions relative to the peptide where only  $\text{Hg}^{2+}$  is bound by DY-NTG. However, a significant amount of  $\text{Cd}^{2+}$  ( $0.59 \mu\text{mole}$ ), besides  $1.96 \mu\text{mole}$   $\text{Hg}^{2+}$ , was also captured from the sample containing 1.0 eq. of all the four metal ions (Figure 7). These data represent ca. 90 % and 24 % binding of the added  $\text{Hg}^{2+}$  and  $\text{Cd}^{2+}$  ions, respectively. Consequently, at  $\text{pH} = 6.0$   $\text{Cd}^{2+}$  can successfully occupy presumably mainly some of the lower affinity sites of the resin, even in the presence of 1.0 eq. of  $\text{Hg}^{2+}$  per peptide. Since  $\text{Cd}^{2+}$  induces a notable quenching of the fluorescence of DY in solution it may potentially act as an interference in the  $\text{Hg}^{2+}$ -binding of this molecular probe at  $\text{pH} = 6.0$  and in samples with sub-stoichiometric  $\text{M}^{2+}$ :peptide ratios. However,  $\text{Zn}^{2+}$  and  $\text{Ni}^{2+}$

cannot compete with  $\text{Hg}^{2+}$  or  $\text{Cd}^{2+}$  in binding at the lower affinity sites.

## Conclusions

In an attempt to investigate the possibility of using simple, very short, bioinspired peptides as fluorescent molecular probes for heavy metal ion sensing, we studied the interaction of a hexapeptide, Ac-DCSSCY-NH<sub>2</sub> (DY), with  $\text{Cd}^{2+}$  and  $\text{Hg}^{2+}$  ions in solution phase and characterized the  $\text{Hg}^{2+}$ -binding ability of the ligand in immobilized form, too. The outstanding affinity of  $\text{Hg}^{2+}$  to the Cys thiolates results in a complete binding of 1.0 eq. of  $\text{Hg}^{2+}$  to the peptide even at pH = 2.0, whereas  $\text{Cd}^{2+}$  complexation starts only at ca. pH 3.5. Both mono- and bis-ligand complexes, with the participation of two and four thiolates, respectively, as the key donors in metal ion binding, are present with  $\text{Cd}^{2+}$  and  $\text{Hg}^{2+}$  above pH ~ 5.5 ( $\text{Cd}^{2+}$ ) and 7 ( $\text{Hg}^{2+}$ ), depending on the applied metal ion to ligand ratio. Both metal ions were found to quench the fluorescence of the Tyr residue of DY at pH = 6.0, nevertheless, this effect is significantly stronger with  $\text{Hg}^{2+}$ , resulting in a 60-65 % drop of the original emission intensity until 1.0 eq. of  $\text{Hg}^{2+}$  is added to the ligand. The decrease of intensity follows a linear trend until reaching a 1:1  $\text{Hg}^{2+}$ :DY ratio even in the presence of 1.0 eq.  $\text{Cd}^{2+}$  that reflects a complete displacement of the peptide-bound  $\text{Cd}^{2+}$  by  $\text{Hg}^{2+}$ . Based on experimental data in solution and related to the fluorescence emission detected at 308 nm, an estimated  $2 \times 10^{-7}$  M value for the limit of detection for  $\text{Hg}^{2+}$  and a linear dynamic range exceeding 2 orders of magnitude were obtained.

The strong  $\text{Hg}^{2+}$ -binding affinity of DY in acidic samples (pH = 2.0) is preserved even in the resin-supported form. The immobilized DY displays a nearly complete  $\text{Hg}^{2+}$ -binding ability up to 1.0 eq. of  $\text{Hg}^{2+}$  per immobilized peptide is added. However, a further, saturation-type increase in the amount of bound  $\text{Hg}^{2+}$  is observed from samples containing  $\text{Hg}^{2+}$  ions in excess (from 1.0 to 3.0 eq. per ligand), suggesting a role of lower affinity binding positions in metal ion binding. This is in a slight contrast to the  $\text{Hg}^{2+}$ -coordinating features of the peptide in solution phase where no signs of dinuclear/oligonuclear  $\text{Hg}^{2+}$ -complex formation is seen. Indeed, binding of  $\text{Hg}^{2+}$  beyond 1.0 eq. per immobilized DY possibly occurs via structures that may exist only under the ligand-rich conditions present in the swollen resin beads and/or by the participation of the PEG chains in metal ion coordination. The presented experimental data, including the remarkable, concentration-dependent quenching effect of  $\text{Hg}^{2+}$  on the fluorescence of the ligand and the efficient  $\text{Hg}^{2+}$ -binding of DY either in solution or immobilized form show the potential of such simple bio-inspired systems in metal ion sensing. In addition to this, our metal ion selectivity experiments suggest that interference from other metal ions may be avoided by using acidic pH.

In our view, this work presents a fine example for the advantages of a combined study of metal binding molecular probes in solution and immobilized forms as this way the altering effects of immobilization on the metal ion binding characteristics can also be unravelled, thereby promoting the development of practical metal ion sensing constructs.

## Experimental

### Materials

The hexapeptide *N*-acetyl-Asp-Cys-Ser-Ser-Cys-Tyr-NH<sub>2</sub> (abbreviated as DY) was purchased from CASLO ApS with a purity of 98.03 %. All other chemicals and solvents, such as *N*- $\alpha$ -Fmoc-O-*tert*-butyl-L-tyrosine, *N*- $\alpha$ -Fmoc-S-trityl-L-cysteine, *N*- $\alpha$ -Fmoc-O-*tert*-butyl-L-serine, *N*- $\alpha$ -Fmoc-L-aspartic acid  $\beta$ -*tert*-butyl ester, 2-(1H-benzotriazole-1-yl)-1,1,3,3-tetramethyluronium hexafluorophosphate (HBTU), *N*-hydroxybenzotriazole (HOBt), Novasyn TG amino resin (all Novabiochem products), pyridine (Merck), *N,N*-diisopropylethylamine (DIPEA), diethylether, triisopropylsilane (TIS), 1,2-ethanedithiol (EDT), piperidine, acetic anhydride, trifluoroacetic acid (TFA), phenol, NaClO<sub>4</sub>, HgCl<sub>2</sub>, ZnCl<sub>2</sub>, CdCl<sub>2</sub>·xH<sub>2</sub>O, NiCl<sub>2</sub>·6H<sub>2</sub>O, Hg(ClO<sub>4</sub>)<sub>2</sub>·nH<sub>2</sub>O, potassium hydrogen phthalate, NaOH solution (all from Sigma-Aldrich), 1-methyl-2-pyrrolidone (NMP), dichloromethane, methanol (Molar Chemicals products), acetonitrile (BDH Prolabo Chemicals) and Cd(ClO<sub>4</sub>)<sub>2</sub>·6H<sub>2</sub>O (Alfa-Aesar) were also of commercial origin and used without further purification. Hg(ClO<sub>4</sub>)<sub>2</sub>·nH<sub>2</sub>O stock solutions were prepared by dissolving the salt in a 0.0600 M perchloric acid. Metal ion stock solutions ( $\text{Hg}^{2+}$ ,  $\text{Cd}^{2+}$ ,  $\text{Zn}^{2+}$ ,  $\text{Ni}^{2+}$ ) were standardized complexometrically except that of HgCl<sub>2</sub>. Stock solutions of HgCl<sub>2</sub> of the desired concentrations were prepared from precise weights of the high purity mercury salt. pH-potentiometric titrations were performed by NaOH titrant, standardized with potassium hydrogen phthalate.

**Synthesis of the immobilized ligand.** The hexapeptide in immobilized form was synthesized on a Novasyn TG amino resin (NTG, 90  $\mu\text{m}$  beads, loading: 0.26 mmole/g) by solid phase peptide synthesis using the Fmoc methodology (Fmoc = 9-fluorenylmethoxycarbonyl). The polyethylene glycol (PEG) polystyrene composite resin was chosen owing to its excellent swelling characteristics in aqueous media. The synthesized peptide molecules were tightly anchored to the resin via amide bonds between the C-terminal Tyr carboxylic groups and the amino functions of the resin which prevented the cleavage of the peptides off the resin under the conditions of the performed experiments. The notation "DY-NTG", referring to the immobilized ligand, is used throughout the text. As a reference compound, "Ac-NTG" (a peptide-free resin with acetylated amino functions) was also prepared and tested in the metal-ion binding studies. The synthesis of the immobilized peptide, DY-NTG, and the reference material, Ac-NTG, was executed according to the steps described in details earlier.<sup>92</sup>

### Methods

**UV absorption and fluorescence measurements.** UV-Visible (UV-Vis) spectra were measured on a Thermo Scientific Evolution 220 spectrophotometer in the wavelength range of 285–400 nm, using a quartz cell with 1.0 cm optical pathlength, equipped with a Teflon cap. The concentration of the ligand was  $1.0 \times 10^{-4}$  M and the metal ion concentration varied between  $5.0 \times 10^{-5}$  and  $2.0 \times 10^{-4}$  M. In order to avoid the eventual oxidation of the ligand, weighed amounts of the peptide were

initially dissolved in a  $1.0 \times 10^{-2}$  M  $\text{HClO}_4$  solution. The concentration of the stock solutions of the ligand was determined by pH-potentiometric titrations. The pH of the samples was adjusted by NaOH solutions and measured by an Orion 710A precision digital pH-meter equipped with a Metrohm Micro pH glass electrode. The water baseline was subtracted from the raw spectra and the spectra were normalized to a  $1.0 \times 10^{-4}$  M peptide concentration to correct for the possible dilution occurring in the titrations.

Fluorescence emission spectra were recorded on a Hitachi-F4500 spectrofluorimeter in the wavelength range of 285 – 400 nm applying an excitation wavelength of 278 nm and slit widths of 5 nm (excitation beam) and 10 nm (emission beam), using a  $1.0 \text{ cm} \times 1.0 \text{ cm}$  quartz cell equipped with a PTFE cap. For samples of  $\text{Hg}^{2+}$ -DY, the experiments were performed at two pH values (pH = 2.0 and 6.0;  $T = 298 \text{ K}$ ) by varying the  $\text{Hg}^{2+}$  concentration ( $c = 0.0 - 75.0 \text{ } \mu\text{M}$ ) and accordingly, the  $\text{Hg}^{2+}$  to peptide ratio. The initial concentration of the ligand ( $c_{\text{DY}} = 28.0 \text{ } \mu\text{M}$ ) varied only as a result of the slight dilution during the titrations. The pH of the samples at pH = 6.0 was monitored during the titrations and corrected, when necessary, by the addition of small volumes of a 0.01 M NaOH solution. There was no need for pH-correction in samples adjusted to pH = 2.0. Experiments were also performed in the presence of  $\text{Cd}^{2+}$  ions where a constant 1:1 concentration ratio of  $\text{Cd}^{2+}$  and DY was maintained. Variation of the fluorescence intensity as a function of pH was monitored in samples containing  $\text{Cd}^{2+}$  and DY in different concentration ratios (0:1, 0.5:1 and 1:1).

The background-subtracted spectra were corrected for the inner filter effects according to the equation:<sup>62</sup>

$$F_{\text{corr}} = F_{\text{obs}} \times 10^{(A_{\text{ex}} + A_{\text{em}})/2}$$

where  $F_{\text{corr}}$  and  $F_{\text{obs}}$  denote the corrected and observed fluorescence intensities, while  $A_{\text{ex}}$  and  $A_{\text{em}}$  are the observed absorbances of the samples at the excitation and emission wavelengths, respectively.

**NMR experiments.**  $^1\text{H}$  NMR measurements were performed on a Bruker Avance DRX 500 spectrometer operating at 500.132 MHz. Samples were prepared in  $\text{H}_2\text{O}$  containing  $\text{D}_2\text{O}$  in 10 % (v/v) and in a few cases in pure  $\text{D}_2\text{O}$  and the spectra were recorded at  $T = 298 \text{ K}$ . The  $z\text{gpr}$  or  $z\text{gcpr}$  pulse sequences were applied for the presaturation of the  $\text{H}_2\text{O}/\text{HDO}$  resonances. The typical concentration of the peptide was  $1.3 \times 10^{-3} \text{ M}$ . The chemical shifts were referenced to TSP-d4 at 0.0 ppm. 1D NMR spectra were recorded by using a recycle delay of 5 s, an acquisition time of 1.64 s, a spectral width of 5 or 10 kHz and 64–128 scans. For samples prepared in  $\text{D}_2\text{O}$  the pH-meter readings (uncorrected by the deuterium effect),  $\text{pH}^*$ , was adjusted to the desired values with NaOD. The recorded spectra were processed by the ACD/Spectrus Processor software.<sup>93</sup> Assignment of the  $^1\text{H}$  resonances of the peptide was accomplished by executing 2D COSY, TOCSY and ROESY experiments. All 2D spectra were acquired with 2048(F2)  $\times$  256(F1) complex points, covering a spectral range of 6 kHz both in F2 and F1. The TOCSY experiments were executed

by using the MLEVPHPR sequence with a mixing time of 70 ms while the ROESY spectrum was recorded with a mixing time of 200 ms. The obtained data were processed by the Bruker software Topspin 3.1.

**pH-potentiometric measurements.** (De)protonation and complex formation processes were studied in aqueous solutions degassed by high purity Ar gas and by applying Ar atmosphere throughout the experiments to avoid the oxidation of the ligand. The pH-potentiometric titrations were carried out by a PC-controlled automatic titration set including a Metrohm Dosimat 765 autoburette, an Orion 710A pH/ISE meter equipped with a Thermo Scientific Orion 8103BNUWP Ross Ultra pH electrode ( $165 \times 6 \text{ mm}$ ). Relative mV values, as pH-meter readings, were converted to hydrogen ion concentrations as described earlier.<sup>85</sup> The protonation and complex formation equilibria were characterized by the following general equilibrium process and the relevant overall formation constant:

where M stands for the metal ion, L for the deprotonated ligand molecule, and H for the protons. Charges are omitted in the above equations for simplicity but can be calculated from the composition of the fully protonated, neutral ligand form,  $\text{H}_4\text{L}$ . Overall formation constants ( $\beta_{\text{M}_\text{p}\text{H}_\text{q}\text{L}_\text{r}}$ ) defined by the above equation were calculated by the PSEQUAD software.<sup>94</sup> Four parallel titrations (60–70 data points per titration) were executed in the absence of metal ions ( $c_{\text{peptide}} \sim 1.0 \times 10^{-3} \text{ M}$ ) for determining the (de)protonation constants of the ligand. The purpose of the titration of the ligand stock solutions was also to obtain the accurate concentration of the peptide. Complex formation constants were evaluated from 3–4 independent titrations in the different metal ion ligand systems (60–100 data points per titration). The applied ratio of the metal ion ( $\text{Cd}^{2+}$  or  $\text{Hg}^{2+}$ ) and the ligand was 0.5:1, 1:1 and 2:1 with the ligand concentrations varying between  $7.3 \times 10^{-4} - 1.0 \times 10^{-3} \text{ M}$ . In the  $\text{Hg}^{2+}$ :DY 2:1 system precipitation occurred even under acidic conditions that prevented to perform titrations under such conditions with this metal ion.

**Experimental conditions and instrumentation utilized in studying  $\text{Hg}^{2+}$ -binding to the immobilized peptide.** Metal ion binding properties of DY-NTG were investigated in 10.00 mL volume samples containing 10.0 mg ( $\pm 1\%$ ) of the resin-supported peptide and the metal ion (typically from a  $\text{HgCl}_2$  stock solution) in a concentration range of  $7.57 \times 10^{-5} - 6.81 \times 10^{-4} \text{ M}$  depending on the type of experiment. The pH of the samples varied between pH = 1.0 and 6.0 and adjusted by perchloric acid solutions ( $c = 1.0 \text{ M}$  or  $0.1 \text{ M}$ ) or by AcOH/NaOAc (pH = 4.0) or MES/NaOH (pH = 6.0) buffer systems. All solutions used for sample preparations were carefully degassed by Ar to prevent the potential oxidation of the peptide. The 10.0 mL samples, placed in glass vessels, were vertically rotated for 120

min by a vertical rotating shaker to allow of a complete equilibration in the metal ion binding process under any conditions. The resin beads were settled by centrifugation for 15 min at 5000 rpm and 2.0 mL aliquots of the solutions were precisely diluted and analyzed for determining the residual metal ion concentrations in the liquid phase of the resin contacted samples.

The applied concentrations of the metal ions were calculated on the basis of the theoretical peptide loading of the resins and the increase of resin mass during the synthesis, according to

$$L = \frac{L_i}{1.0 + L_i \times M_{ad}}$$

where  $L$  is the loading of the resin after the completion of the synthesis,  $L_i$  stands for the initial loading value and  $M_{ad}$  represents the molar mass of the added peptide fragment. Considering a nearly 100 % coupling efficiency in the synthesis, the above formula gives  $0.227 \times 10^{-3}$  and  $0.267 \times 10^{-3}$  mole/g theoretical loadings for DY-NTG and Ac-NTG, respectively. Previous experiences with the very same Novasyn TG amino resin functionalized by a closely related peptide clearly showed the usability of the above estimation of the loading values. Concentrations of the metal ions in the studied samples were set to achieve a desired metal ion to ligand ratio, according to the theoretical loadings.

All of the presented data are the results of duplicate experiments except that of the  $Hg^{2+}$  binding capacity of Ac-NTG obtained from five repetitions.

Determination of metal ion concentrations in the solutions was accomplished on an Agilent 7700x inductively coupled plasma mass spectrometer (ICP-MS). The instrument was used in the helium mode of the OSR<sup>3</sup> collisional cell. Calibrating solutions were prepared from a certified mono-elemental Hg stock standard solution (CaPurAn M324.5NP.L1) and trace quality deionized lab-water (Millipore Elix Advantage 5 + Synergy) to perform a multi-point calibration. The mass peaks of <sup>201</sup>Hg and <sup>111</sup>Cd isotopes were utilized for quantitation with <sup>209</sup>Bi and <sup>103</sup>Rh signals, respectively, as internal standards (using the Agilent No. 5188-6525 internal standard mix). Prior to all measurements, the autotuning of the ICP-MS instrument was performed according to manufacturer specifications, using standard solutions supplied by Agilent. All labware was cleaned before use with ultratrace grade nitric acid and hydrochloric acid (BDH Aristar Ultra), thoroughly rinsed by the above trace quality deionized lab-water and finally dried under a laminar flow clean bench.

## Conflicts of interest

There are no conflicts to declare.
