Southwestern Hungary

### ABSTRACT

A comprehensive and detailed picture was gained about the historical events and the natural environment of Southwestern Hungary at the beginning of the 5th millennium BC. The archaeological site at Sormás-Török-földek provided a favoured unique opportunity to study the formation process of the Middle Neolithic Sopot and Late Neolithic Lengyel culture. Wood charcoal analysis provided site-related information about the natural milieu of the site. Anthracological analysis has not been carried out in Southwestern Hungary so far, whereby more than 3600 fragments of charred wood remains were identified. Our dataset was compared to pollen analytical, archaeobotanical and archaeological data to create a more accurate vegetation picture for this period of time and to reconstruct the utilization of wood during Middle and Late Neolithic. Charcoal assemblage reflects the composition of the woodland around the site. Based on the results a thermophilous *Quercus* forest mixed with *Fagus*, *Fraxinus*, *Acer*, *Alnus* and *Ulmus* existed in the study site during the Middle and Late Neolithic and different types of wood were used for fire wood and for construction purposes as well. Anthracological analysis of samples from Sormás-Török-földek enabled a more accurate vegetation reconstruction for the study site by the comparison to previously known pollen analytical data and added extra information regarding the local vegetation and wood utilization for the Middle and Late Neolithic.

### 1. Introduction

During the M7 motorway excavations between 1999 and 2007 many important prehistoric settlements were revealed in Zala County, Southwestern Hungary (Transdanubia). This territory played an intermediating role between the Balkans and Central and Eastern Europe during Neolithization. Cultural waves from the Balkans passed through Southwestern Transdanubia in three successive waves beginning from the appearance of the Starčevo culture in the Early Neolithic. The emergence of the LBK was the result of the second wave arriving from the south in the Middle Neolithic, inspiring the spread of the LBK into Central Europe. The formation of the Lengyel culture can be connected with the third cultural wave of southern origin. Furthermore, the development of the Middle Chalcolithic Balaton-Lasinja culture can also be correlated with similarly strong cultural impacts from the south (Bánffy, 1995, 2004, 2013). One of the settlements, Sormás-Török-földek, represents the material remains of the Starčevo, Linear Band Pottery Culture

(LBK) and both the Sopot and Lengyel cultures dated to the Early, Middle and Late Neolithic of the Carpathian Basin. The find assemblage on the site at Sormás-Török-földek dated to the turn of the Middle and Late Neolithic provided an opportunity to redraw the picture about the Transdanubian Sopot culture formed earlier on the basis of sporadic data.

As it was generally viewed, the two main components in the formation of the culture were the Central European (Transdanubian) Linear Band Pottery culture (LBK) and the Sopot culture. It has also been accepted that there was genetic continuity between the LBK and the Lengyel cultures, in the first instance on the grounds of the high scale coincidence of the territories of both cultures; even though no factual pieces of evidence of the continuity have been available. Transdanubia, South-Western Slovakia and the western part of Burgenland comprise the territory of the emergence of the Lengyel culture (Kalicz, 2001, 2007; Čižmař et al., 2008), where, during the period prior to the emergence of the Lengyel culture, different territorial groups of the LBK had settled: the Keszthely, the Music Note, the Zselíz groups and the Šarka style. The presence of the Transdanubian Sopot culture – on the grounds of the settlement pattern earlier thought to be loose and dispersed – seemed to be hardly at all correlated with that of the LBK, but at the same time the high scale similarity found in the material culture proved that there was direct correlation between the Sopot and the Lengyel cultures. Accordingly, the genesis of the

<sup>1</sup> Tel.: +36 83 312 351.

Lengyel culture was considered as a process taking place on the multicultural substrate of the LBK groups in which the Sopot culture played a catalyser role fostering transformations.

Thanks to the intensive research activities related to the M7 motorway excavations it became clear that the Transdanubian Sopot culture had played a much more determinative role in the formation process of the Lengyel culture as it was supposed earlier (Kalicz et al., 2007; P. Barna, 2007a; Kalicz et al., 2012). Therefore the re-evaluation of the Sopot culture as one of the basic components of the Lengyel culture (Kalicz, 1988) made it also necessary to revise the earlier opinions and statements made about the formation of the Lengyel culture. This was even more motivated by the fact that on the site at Sormás-Török-földek, besides the find material from the Sopot culture, the find material from the formative phase of the Lengyel culture was also found. The comparison of the altogether three ditch-systems excavated on the two Sormás sites made possible to approach the period at the turn of the Middle and Late Neolithic also from a new aspect.

The archaeological findings obtained from the site consist of not only classical archaeological material such as pottery, stone, bone and antler artefacts but anthropological, archaeozoological, anthracological and archaeobotanical materials as well that are very important from a geoarchaeological point of view.

Wood charcoal analysis is an applied method in Quaternary research that provides information about vegetation changes. It helps to reconstruct the vegetation cover for a certain time period via the analysis of the anatomical character of charred woody tissues and cells (Greguss, 1945, 1972). Its significance lies in the fact that it makes the reconstruction of the former local flora possible adding extra information to complex palaeoecological reconstructions. Archaeoanthracology (Vernet, 2002) focuses on the wood used by the different cultures and populations (Jansen and Nelle, 2012). It enables us to study the anthropogenic impact on vegetation and plant communities and the usage of wood material (Neumann, 1992; Kreuz, 1992). The presence of humans supposes the transformation of the vegetation in the surroundings of the settlements. Gathering, plant cultivation, animal husbandry, the need of firewood and the increasing population all contribute to trigger deforestation. So vegetation development is highly influenced by human activities in the vicinity of former settlements.

Anthracological analyses have not been carried out in this area before. Due to the development of Quaternary research during the last decades in Hungary (Sümegi, 1989, 1997, 1998, 2001, 2003) anthracological studies became significant in palaeoenvironmental studies (Rudner, 1994, 2001, 2002; Sümegi and Rudner, 2001). However, it is still a less known area amongst archaeologists and

palaeoecologists in Hungary. Furthermore, anthracological analysis is lacking in most palaeoecological studies.

Our aim was to outline the palaeoecological background of the Middle–Late Neolithic site in Southwestern Hungary during different habitation phases of Neolithic populations. We attempted to complete the results of the previous pollen analyses (Juhász, 2004, 2007) and to reconstruct the former local vegetation by the examination of wood macro remains and the results of palynological data. Furthermore, to bring to light which wood taxa were used by Neolithic populations and to investigate their impact on the vegetation. At the same time, we would like to draw attention to the importance of the method and give extra data to previous palaeoecological studies in Southwestern Hungary. In other respect the combination of the different methods might strengthen or complete the results of previous analyses so we can achieve a more accurate vegetation picture for the site on a local and regional scale and have a sight into the usage of wood during Neolithic.

## 2. Study area

The site at Sormás-Török-földek is situated on the southern side of a north-south oriented natural elevation (Fig. 1), about 182 m above sea-level. The Mántai Stream borders this elevation in the east. Another Neolithic site named Sormás-Mántai-dűlő is situated on the other bank of the stream. Its height above sea-level is about 164.5 m. Both Sormás sites are very close to each other not only in a physical, but also in a chronological and cultural sense (P. Barna, 2007a).

The climate of the study area is temperate cold and temperate humid. The south part of the region enjoys a Subatlantic, while that of the southwest a Subalpine climate. The mean annual temperature is 9–9.8 °C. The mean annual precipitation on the southwestern and southern part is 800 mm (Marosi and Somogyi, 1990).

The vegetation cover is quite diverse as a consequence of the different climatic and soil characters. On the south and southeast part of the county sessile oak forest mixed with hornbeam trees (*Querco petraeae-Carpinetum*), beech grove (*Vicio oroboidi-Fagetum*), pubescent and Austrian oak forest (*Quercetum pubescenti-cerris*), dwarf willow forest (*Salicetum triandrae*), willow-poplar gallery forest (*Salicetum albae-fragilis*) and oak-ash-elm gallery forest (*Querco-Ulmetum*) exist (Marosi and Somogyi, 1990).

The typical soil types are as follows. On higher loess covered surfaces lessivage brown forest soil and chernozem brown forest soils have developed. On the edges of river valleys leached brown forest soil, along rivers and on alluvial deposits hydromorph soil prevails. On

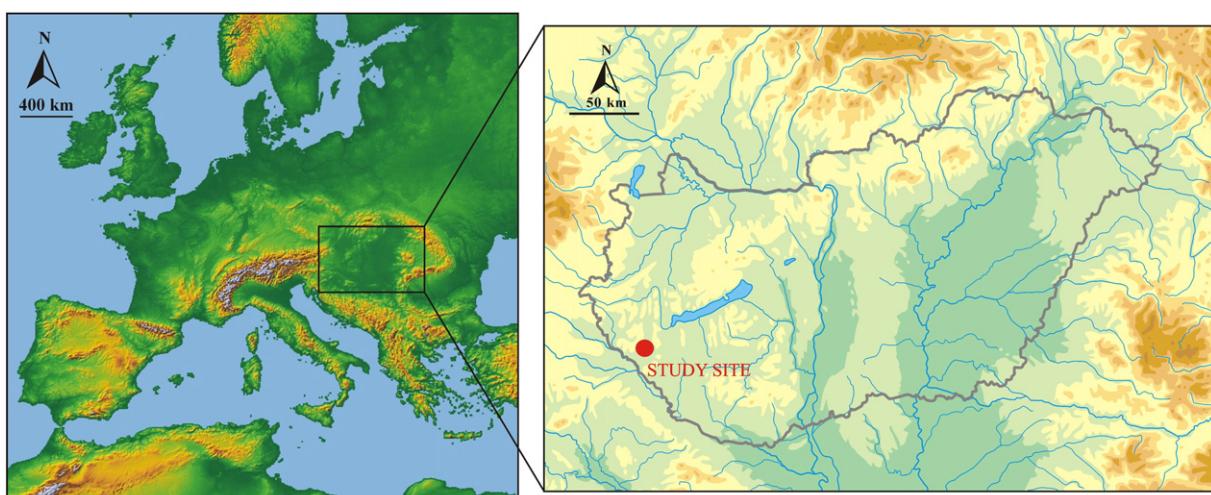

Fig. 1. Location of Sormás-Török-földek.

periglacial sediments and on loess covered surfaces pseudogley brown forest soils developed (Marosi and Somogyi, 1990).

### 3. Archaeological background

#### 3.1. The Neolithic sequence of Western Hungary

Due to the fact that cultural development was different in the western and eastern half of the Carpathian Basin prior to the Late Copper Age we focus on the Neolithic sequence of the western part of Hungary called Transdanubia (Biró, 2003).

The dawn of the Neolithic is associated with the appearance of the Starčevo culture of southern origin in the first half of the 6th millennium (Kalicz, 1990). It is debated to what extent the local Late Mesolithic population of Transdanubia took part in the formation process of the earliest food-producing culture of the region (Bánffy, 2004; Oross and Bánffy, 2009). A unique site of the culture with more than 400 features, dated to the final phase of the Starčevo culture, was discovered and excavated at Alsónyék-Bátaszék (Bánffy et al., 2010).

The Middle Neolithic period corresponds to the life of the LBK between roughly 5500 cal BC and 5000 cal BC (Oross and Bánffy, 2009). Several developmental phases could be distinguished in the LBK sequence of Transdanubia (Table 1).

The gradual formation of the LBK can be dated around 5500 cal BC. According to an “integrationist theory”, it took place on the ground of an essentially Mesolithic subsistence, complemented by Neolithic elements brought here by migrant late Starčevo groups (type site of the formative phase: Szentgyörgyvölgy-Pityerdomb) (Oross and Bánffy, 2009; Bánffy and Oross, 2010). The end of the LBK falls around 5000/4900 cal BC and coincides in time with the emergence of the Lengyel culture.

During the Late Neolithic period of Transdanubia, people of the Keszthely group along with the Sopot culture, migrating from the south to Transdanubia, took part in the multicultural formation process of the Late Neolithic/Early Copper Age Lengyel culture (around the turn of the 6th to the 5th millennium). The absolute chronology of the formative phase of the Lengyel culture can be determined on the basis of radiocarbon dates obtained from the sites at Esztergályhorváti (4990–4710 cal BC (68,2%)) and Sormás-Török-földek (4780–4690 cal BC (68,2%)) (Stadler and Ruttay, 2007; P. Barna, 2007a; P. Barna and Pásztor, 2011, Table 1.). The classical phase of the Lengyel culture (previously named as phase I) is characterised by the use of red paintings on the pottery. Radiocarbon dates are not available from this developmental phase to date.

The next developing phase of the Lengyel culture, characterised by the use of crusted white paintings on the pottery, can be dated only by conventional radiocarbon dates which seem to be too young. Therefore they are not comparable with the calibrated dates (see

e.g. Zalavár-Mekenye). The last (“unpainted”) phase of the Lengyel culture (phase III) falls already into the Early Cooper Age. It can be dated on the basis of radiocarbon dates obtained from a site at Zalaszentbalázsz-Szőlőhegyi mező between 4690–4450 cal BC (68,2%); 4720–4360 cal BC (95,4%) and 4450–4370 cal BC (68,2%); 4690–4340 cal BC (95,4%) (Oross, Marton, Whittle, Hedges and Cramp, 2010, Table 2).

#### 3.2. The Late Neolithic archaeological material of the site at Sormás-Török-földek

The Sopot and early Lengyel potteries mostly share common forms and decorations. There are only a few differences between them. The high similarity of ceramics of the two cultures sometimes hampers correct assignment. The ratio of the given forms, decoration motifs and especially the different coloured painted pottery are determinative for the inner dating of the Sormás-Török-földek site. The high number of finds considered to be of ritual character found in Sormás-Török-földek, is a feature that could be observed also in other late Sopot sites in Southwestern Transdanubia (e.g. Sormás-Mántai-dűlő, Petrivente, Becsehelyi I., see Kalicz et al., 2007; P. Barna, 2007b). This feature compared to Sopot sites in Slavonia and in other territories of Croatia, must be attributed to the unique territorial and chronological characteristics of the Southwestern Transdanubian Sopot sites.

Foreign pottery of Korenovo, Butmir and Vinča style came to light in both Sormás sites. The most intense foreign influence can be recognised from the Butmir culture, which can be shown on various levels (P. Barna and Biró, 2009; P. Barna, 2009).

A large amount of stone materials was found on both Sormás sites. Examinations contributed greatly to the clarification of the communication systems of the two Sormás settlements. Compared to the excavation area's size the frequency of stone artefacts is low. Characteristic elements of the raw material spectrum are the grey flint and radiolarites. Apart from these types of raw materials, known from the Bakony and the Mecsek mountains, a raw material from an unidentified source is also significant, possibly pointing to southern connections. Long distance raw materials primarily occur amongst polished stone tools (greenschist, hornfels), but some long distance materials also occur amongst the typical regional raw materials for chipped flint tools, from outside of the Carpathian Basin: Lessini flint, Prut flint and Jurassic Krakow flint (P. Barna and Biró, 2009).

#### 3.3. Habitation phases

On the basis of inner evidences four different habitation phases with further sub-phases can be distinguished in the site at Sormás-Török-földek (subphases No. 1–4). The earliest habitation phase is composed by two little settlements represented by a few sporadic features of the Starčevo culture (1st habitation phase; 6000/5900–5500 cal BC). The

**Table 1**

Chronology of Early, Middle and Late Neolithic cultures and habitation phases of Sormás-Török-földek in Southwestern Transdanubia.

Age	Archaeological period	Archaeological data from the site at Sormás-Török-földek		
		Habitation phase	Sub-phase	Absolute chronology
4900–4700 cal BC	Late Neolithic (the formative phase of the Lengyel culture)	4th habitation phase	4b	VERA-3538: 4780–4690 cal BC (68,2%); 4830–4610 cal BC (95,4%)
			4a	no data
5000–4500 cal BC (Kalicz, 2007)	Middle and Late Neolithic transition (Sopot culture)	3rd habitation phase	3b	VERA-3539: 4790–4700 cal BC (68,2%); 4840–4610 cal BC (95,4%); VERA 3098: 4910–4790 cal BC (68,2%); 4950–4720 cal BC (95,4%)
			3a2	VERA-3535: 5050–4850 cal BC (68,2%); 5210–4830 cal BC (95,4%)

find material of both Starčevo settlements can be dated to the beginning of the late phase of the culture (beginning of the Spiraloid B phase) (P. Barna, 2004). The following habitation phase belongs to the Keszthely group of the LBK (2nd habitation phase; 5500–5000 cal BC). Only a few settlement features of this phase could be identified.

The Late Neolithic period of the site can be divided into two phases. The 3rd inhabitation phase (5000–4500 cal BC) is made up by the settlement of the Sopot culture. There were at least three inhabitation phases of the Sopot culture in the Török-földek site (settlement phases 3a1, 3a2 and 3b) (P. Barna, 2010). The longer duration of the settlement of the Sopot culture may be attested by a relatively greater diversity of house types. Not only single places of houses could be determined, but some household clusters consisting of the unity of a dwelling and a smaller, accompanying building of probably economic function. The inhabitation is concentrated in the inner territory of enclosure No. II (P. Barna, 2010). The 4th inhabitation phase (4900–4700 cal BC) corresponds to the settlement of the Lengyel culture. The 3rd and the 4th inhabitation phase are connected strongly to each other, just like both cultures. The cultural and chronological connections between the 3rd and the 4th inhabitation phase are reflected in the context of the two enclosures in the same way as in the material culture. As it is attested by the find material (first of all the pottery) it is not possible to draw a categorical dividing line between the Sopot and Lengyel cultures.

The 4th habitation level is constituted by the formative and the early phase of the Lengyel culture (sub-phases 4a and 4b), which was also significant, similarly to the preceding Sopot-settlement. This is proven not only by the establishment of the northern enclosure (Enclosure No. I, Fig. 2), groups of houses and the abundance of the find material, but also by the fact, that it is one of the biggest, central-type settlement of the formative phase of the Lengyel culture.

The earlier sub phase (sub-phase 4a) can be identified chronologically and culturally as the formative phase of the Lengyel culture or Lengyel 1a phase (Kalicz et al., 2007). Enclosure No. I was constructed in that time and was used only in this settlement phase. The dwelling-houses of this inhabitation phase were built still inside Enclosure No. II. The early Lengyel culture settlement is supposed to be long lasting and it may be presumed that it survived the initial phase of the culture (sub-phase 4b). This means that the youngest features of the settlement may be dated to the transition between Lengyel 1a and 1b phases (or even the beginning of Lengyel 1b phase).

The elimination of Enclosure No. I – by the homogenous filling – was the result of a conscious levelling and not a longer, natural filling in process. However, its reason is unknown, due to lack of clues for the possible causes for abandoning the settlement. It can be stated with certainty that as the whole life of the settlement was characterised by a longer, uninterrupted development, its end was neither caused by hostile attack, nor by the appearance of foreign ethnic groups. No traces of destruction layers or unburied bodies were found, which could indicate warfare. The early Lengyel period was followed by a several hundred year-long habitation hiatus, the end of which is indicated by

a short habitation phase of the Middle Chalcolithic Balaton-Lasinja culture represented by a few settlement features.

#### 4. Material and methods

##### 4.1. Charcoal analysis

During the archaeological excavation preceding the M7 motorway macrobotanical material was obtained from the archaeological site Sormás-Török-földek. Sediment profiles were created (Sümegi et al., 2011a) at the archaeological sites and it was possible to study the settlement levels of the individual cultures and soil horizons.

Charcoal remains collected at the site originate from different archaeological features, amongst which there are refuse pits, extremely large pits used for clay mining, diverse structural elements of houses such as postholes and foundation trenches, ditches encircling houses (or building sites of dwelling-houses) and the ditches of the enclosures.

The archaeobotanical material was obtained from uniformly 2.7 kg of samples (Sümegi et al., 2011a) according to the German standards (Jacomet and Kreuz, 1999). The double flotation method of Gyulai (2001) was adopted, using 0.5 and 0.25 mm Ø mesh size sieves. Material is initially passed through the 0.5 mm mesh size sieve. The residue is then passed through the next sieve of smaller mesh size to retrieve smaller size remains as well.

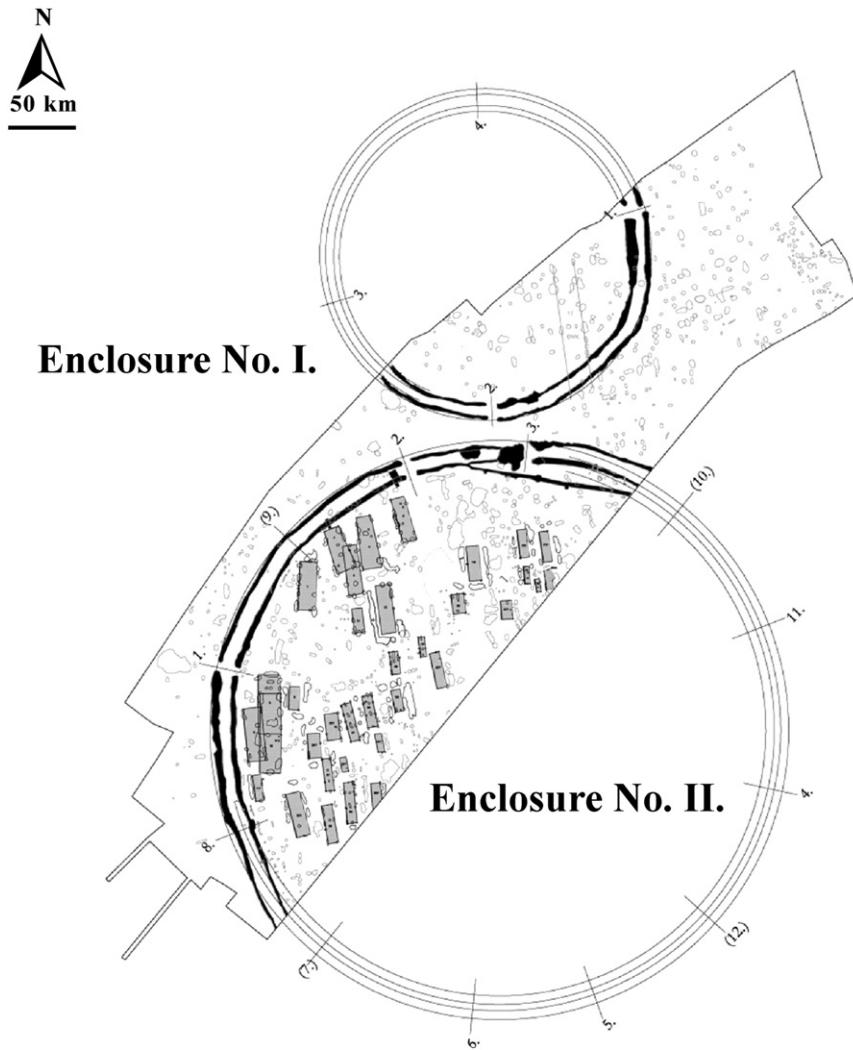

The remains were then sorted for archaeological, archaeozoological and archaeobotanical analysis. Macrobotanical analysis was carried out on charcoals and seeds alone. Charcoal samples were selected and counted. We represent the charcoal fragment counts after Chabal et al. (1999). In case of floated samples it makes no difference if we count or weigh the amount of charred wood remains (Asouti and Austin, 2005).

Charcoals were identified using polarisation microscope with magnifications 100×, 200× and 500×. The taxon identification was carried out using the reference books of Pál Greguss (1945, 1972) and Fritz Hans Schweingruber (1990).

The age of the charcoal samples were obtained according to the archaeological findings. The most precisely dateable features are the refuse pits and the foundation trenches of houses (if they contain datable artefacts). The extremely large pits used for clay mining, ditches encircling houses or building sites of dwelling-houses and the ditches of the enclosures are less appropriate for accurate dating regarded that they were opened and used for longer time. These features are large and deep in general, several times they have more than ten excavating layers. Samples taken from such large features can be dated precisely only if they originate from an unequivocally datable layer.

##### 4.2. Pollen analysis

In order to get a more accurate vegetation reconstruction the pollen analytical data of Juhász (2004, 2007) were adopted and the results of

**Fig. 2.** Enclosures No. I and II. at Sormás-Török-földek (P. Barna, 2007a).

anthracological analysis was compared to the pollen sequence of Zalavár as it is the closest undisturbed core to the archaeological site where pollen analysis was performed (Fig. 3).

#### 4.3. Radiocarbon analysis

The radiocarbon dates (Table 2) obtained from the sites at Sormás-Mántai-dűlő and Sormás-Török-földek compared to more data from other sites from the region has already been published (P. Barna, 2007a; P. Barna and Pásztor, 2011). The majority of the dates fall into the periods of the Sopot culture and to the formative phase of the Lengyel culture. Two data refer to the LBK. One date refers to the older phase of the LBK, another one to the Kesztely-group. Both dates of the LBK diverge clearly from the others and are in good concordance with data published recently by Oross and Bánffy (2009). The dates referring to the Sopot and the Lengyel cultures are very close to each other; some of the Sopot dates cover those of the Lengyel culture. This problem was recognized also in other sites in Southwestern Transdanubia (Kalicz et al., 2007). Out of the dates overlying each other only the oldest dates of the Transdanubian Sopot culture hang out, which go back to the end of the 6th millennium BC. As for dates referring to the formative phase of the Lengyel culture we used a single date obtained from Sormás-Török-földek (Feat. 93), which fits in the time period indicated by the sequence of 7 data of the Esztergályhorváti

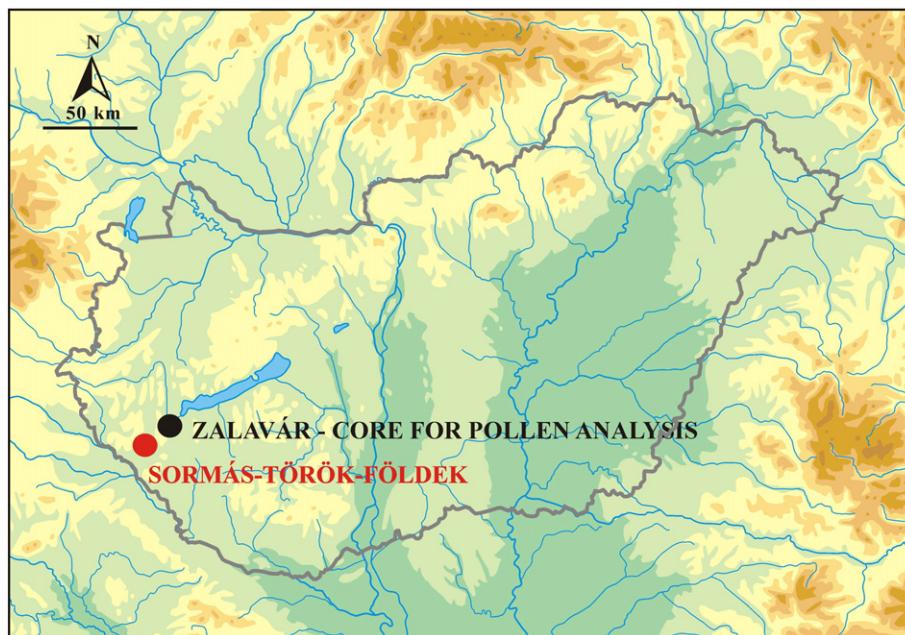

common grave of the same time range (P. Barna, 1996; Bronk-Ramsey et al., 1999; Stadler and Ruttkay, 2007).

#### 5. Results of charcoal analysis

The total number of samples deriving from the features of the archaeological excavations is 239. The total volume of samples was 75,697 cm<sup>3</sup>. However, the anthracological material of 123 samples was unidentifiable due to bad preservation or overburning of charcoal fragments or origin from undated archaeological features. Thus the number of samples containing identifiable charcoal fragments is 116. Results of anthracological analyses are presented in Table 3 as counts and percentage ratio of charcoal fragments. The total amount of identified charcoal fragments is 3693 with 6 identified genera and 1 group that was defined as Pinaceae due to bad preservation.

Charcoal fragments deriving from the 1st habitation phase (Starčevo; 6000/5900–5500 cal BC) indicate *Quercus* dominance. However the total amount of charcoal derives from this archaeological horizon is low (132 pieces of fragments). Unfortunately, no charcoals were retrieved from archaeological features belonging to the 2nd habitation phase (5500–5000 cal BC).

The total number of charcoal fragments deriving from the 3rd habitation phase (Sopot culture; 5000–4500 cal BC) is 1746 pieces. It indicates a very high *Quercus* ratio of 90.5%. In addition charred wood remains of Pinaceae, *Fagus*, *Fraxinus*, *Ulmus* and *Alnus* were found.

**Fig. 3.** Location of Sormás-Török-földek (red square) and the core for pollen analysis (black square).

A total of 1815 pieces of fragments turned up from archaeological features belonging to the period of the 4th habitation phase (Lengyel culture; 4900–4700 cal BC). It points to *Quercus* dominance as well, however, its ratio decreased to 81%. Besides the remains of oak, *Acer*, *Alnus*, *Fagus*, *Ulmus* and *Fraxinus* charred wood remains occurred.

Tables 4 and 5 present charcoal distribution with regard to archaeological features. It can be clearly seen that during the 3rd habitation phase (Table 4) *Alnus*, *Fagus*, *Fraxinus* and *Quercus* are found in refuse pits, while *Quercus* and *Ulmus* are mainly confined to extremely large pits used for clay mining. *Fagus*, *Pinaceae* and *Quercus* charcoals occur in diverse structural elements of houses, *Quercus* appear in ditches encircling houses and in the ditches of the enclosure.

During the 4th habitation phase (Table 5) *Acer*, *Alnus*, *Fagus*, *Quercus* and *Ulmus* occur in refuse pits and *Quercus* in extremely large pits used for clay mining as well. *Alnus* and *Quercus* appear in diverse structural elements of houses, such as postholes. *Acer* and *Quercus* are found in the ditches of the enclosure, while *Acer*, *Fraxinus* and *Quercus* appear in a scarp pit as well.

## 6. Discussion of the vegetation cover during the Neolithic around Sormás-Török-földek

### 6.1. Discussion of the charcoal results with the archaeological background

Charcoal fragments deriving from the 1st habitation phase (Starčevo culture) that were disturbed later by new settlers of the Sopot and

Lengyel culture point to *Quercus* prevalence (Fig. 4). However, only a small amount of charcoal occurred in features of these periods. Probably two other archaeological features that contained only ash and charcoal belong to this period as well, although their dating is problematic due to the lack of ceramics.

We have no data regarding the 2nd habitation phase since charcoal fragments did not occur in closed archaeological features that belong surely to LBK.

Most of the analyzed samples belong to the 3rd and 4th habitation phases. Six different genera were found in archaeological features of the 3rd habitation phase of the Sopot culture. 90.5% of charred wood remains belong to *Quercus*; besides *Fagus*, *Ulmus*, *Pinaceae*, *Alnus* and *Fraxinus*. The high number of *Quercus* charcoal and their source archaeological features (refuse pits, structural elements, and ditches) indicate that it was available in large quantities in the surroundings of the settlements and was used for fuel wood and construction purposes as well. *Fagus* remains occurred in diverse structural elements of houses and in refuse pits so it was used as construction wood and fuel wood. *Pinaceae* occurred in diverse structural elements so it might be construction wood. *Alnus* and *Fraxinus* appeared in refuse pits indicating its utilization as fuel wood. Moreover, *Alnus* also turned up in extremely large pits used for clay mining, such as *Ulmus* indicating their role as firewood.

The 4th habitation phase indicates *Quercus* dominance similarly to the previous phase although with a lower ratio (81%). Based on the source archaeological features (refuse pit, extremely large pit used for clay

**Table 3**

Summary of absolute and percentage fragment counts of charcoal fragments at the rescue excavation of Sormás-Török-földek.

Charcoal taxa	1st habitation phase		2nd habitation phase		3rd habitation phase		4th habitation phase		Total number
	No.	%	No.	%	No.	%	No.	%	
<i>Acer</i>							200	11	200
<i>Alnus</i>			21	1.2	8	0.4	29		
<i>Fagus</i>			62	3.5	56	3.1	118		
<i>Fraxinus</i>			16	0.9	32	1.8	48

mining, diverse structural elements of houses, ditches encircling houses, ditches of the enclosure and in a sacrfy pit), it was used as construction wood and fuel wood similarly to the 3rd habitation phase. Similar wood genera occurred to that in the 3rd phase, with the only exception of the absence of *Pinaceae* and the presence of *Acer*. This later turned up in refuse pits, in the ditches of the enclosure and in a sacrfy pit. Half of the samples of *Acer* appeared in the late phase of the 4th habitation phase (P. Barna, 2010). Moreover, all of the archaeological features where *Acer* charcoal occurred is located in the vicinity of Enclosure No. I that indicate also the late phase of the 4th habitation phase.

*Fagus* and *Ulmus* turned up in refuse pits so they might have been utilized as fuel wood. *Alnus* appeared in a low ratio in a posthole indicating its utilization as construction wood and in a refuse pit. *Fraxinus* derive from one archaeological feature that belong to the late phase of the 4th habitation phase that presumably was used for a ritual activity (P. Barna, 2010). The structure of this archaeological feature was continuous and its charcoal and ash filling, rich and unique findings (anthropomorphic figurines, askos, bucranium) may point iterative ritual act of burning. *Fraxinus*, *Quercus* and *Acer* (from top to bottom) appeared in different layers of the feature but they all belong to the late phase of the 4th habitation phase. Potential connections between the ritual use of the object and the presence of tree species (*Acer*, *Fraxinus* and *Quercus*) is a question of debate.

## 6.2. The comparison with the regional pollen record and the on-site archaeobotanical material

Palynological results (Figs. 5 and 6, after Juhász, 2004, 2007) indicate *Quercus* dominance similarly to the anthracological results, so deciduous oak woodland existed at the beginning of the Neolithic (6000 BC) in the study area. The increase of *Betula* and *Pinaceae* pollen coincide with the pre-Neolithic and the beginning of the Neolithic period. *Pinus* pollen peak may point to the spread of pines in the area. However, pine pollen grains have air sacks following that they can be transported over long distances. *Pinus* is a pioneer species that establish fast on cleared areas. The rise of *Betula* in the pollen diagram indicates deforestation beforehand and succession as it is also pioneer that can be spread easily and fast on cutoff areas (Jansen and Nelle, 2012) so cyclic forest burning may have occurred. Deforestation resulted in the opening up of the forest canopy where *Corylus* could spread on forest edges as the high value of *Corylus* pollen indicates (Willis et al., 1997, 1998; Magyari et al., 2002; Sümegi, 1998, 2004a, 2013; Sümegi et al., 2004;

Juhász, 2007). Its ratio is cyclic and is in contradiction with *Quercus* pollen ratio. Other study of this site (Juhász, 2004) indicates high ratio of *Pteridium* spore in the profile between 255–200 cm that corresponds to the period between 6600–6160 cal BC and 6220–6020 cal BC (95.4%) (Juhász, 2004). This can be interpreted as a “preneolithic human influence” (Juhász, 2004) that resulted in the opening up of the forest canopy.

Charcoal data of the 3rd and 4th habitation phases (Middle and Late Neolithic) correlates well with pollen analytical data, some differences derive from the regional nature of pollen which may hide distinct local vegetation characteristics. Differences relate to the absence of *Corylus*, *Tilia* and *Carpinus* charcoals that are present in the pollen material. The lack of *Tilia* in the charcoal assemblage is not surprising as it is unsuitable as fire wood (Kreuz, 1992). However, in other Neolithic sites in Germany (Jansen and Nelle, 2012) *Tilia* is well represented. *Carpinus* is rather sporadic in the pollen diagram and probably was sporadic also in the forest stand, as well as *Tilia*. The reason for the high amount of *Corylus* pollen is may be its fast growth and its ability to produce shoots after cutting (Jansen and Nelle, 2012) such as *Quercus* and/or the abovementioned forest burning activity. However, neither *Corylus* charcoals nor fruits have been found in this area yet.

Pollen of herbaceous plants such as *Artemisia*, *Compositae* and *Chenopodiaceae* indicates human activity. Pollen of cereals appeared only in the Copper age, however cereal seeds were found in Sormás-Török-földék site. *Triticum monococcum* (10 pieces), *Triticum dicoccum* (41 pieces), *Triticum spelta* (5 pieces) and *Hordeum vulgare* (5 pieces) appeared. Further cultivars such as *Pisum sativum* (3 pieces), *Lens culinaris* (5 pieces) and *Linum usitatissimum* (36 pieces) seeds occurred from Neolithic features (Sümegi, 2007b). Besides these, 287 pieces of fragments that belong to cultivated cereals (*Gramineae cultae*) occurred. However, their genus or species identification was not possible. Weeds indicating cultivated lands, roads and settlements appeared, such as *Chenopodium album* and *Sambucus racemosa*. The presence of *Bromus secalinus* supports the cultivation of cereal since it indicates cultivated area even if cereal pollen or seeds do not occur. *Ononis spinosa* seeds were also found that point to animal husbandry. So besides plant cultivation, livestock farming was present in the Neolithic settlement (Sümegi, 2007b).

Intensive deforestation is characteristic only from the Copper age, since the ratio of NAP (non-arboreal pollen) and the decrease of AP (arbour pollen) pollen occur from this period of time (Fig. 5, 140–150 cm).

**Table 5**

Archaeological features and fragment counts of genera during the 4th habitation phase.

4th habitation phase	<i>Acer</i>	<i>Alnus</i>	<i>Fagus</i>	<i>Fraxinus</i>	<i>Quercus</i>	<i>Ulmus</i>	Total number

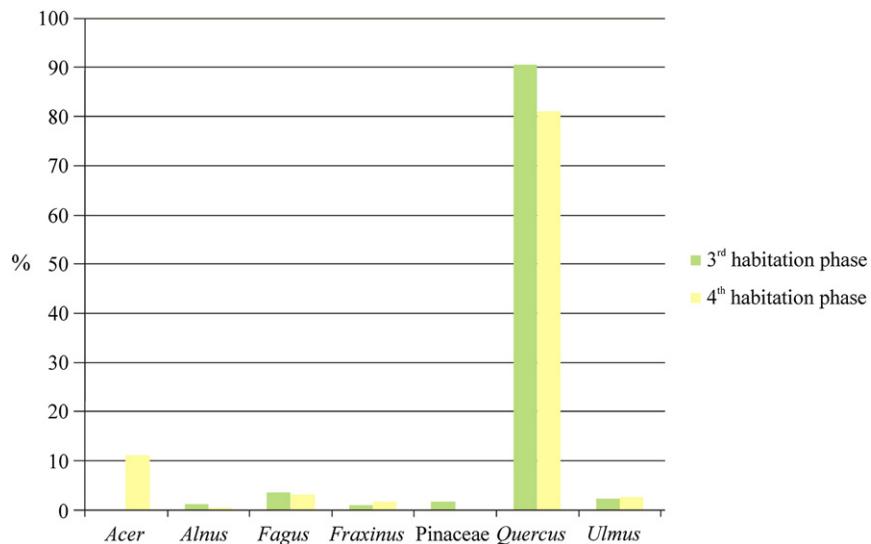

Fig. 4. The comparison of charcoal occurrence in habitation phases 3 and 4.

### 6.3. Wood selection and taphonomy

The large number of *Quercus* charcoal raises questions regarding the selection of wood and fragmentation of charcoal. The composition of charcoal assemblage and the relative frequencies of taxa do not necessarily indicate the composition of past vegetation (Figueiral Mosbrugger, 2000). Rather, it provides data regarding the taxa used by human population (Willcox, 2002). Therefore the influence of human selection must be considered. Fuel wood for domestic purposes is generally collected from the nearest

resources (principle of least effort), so the charcoal composition reflects the availability of the surroundings of settlements (Shackleton and Prins, 1992). Based on this, availability is the principal factor regarding domestic firewood selection (Chabal, 1992). On the contrary, construction purposes demanded specific wood selection (Western, 1971). However, it is assumed that for the Neolithic the charcoal assemblage represents the available wood in the vicinity of the settlements (Jansen and Nelle, 2012). In view of fragmentation after Chabal (1997) the fragmentation process of charcoal is the same for all species in the case of

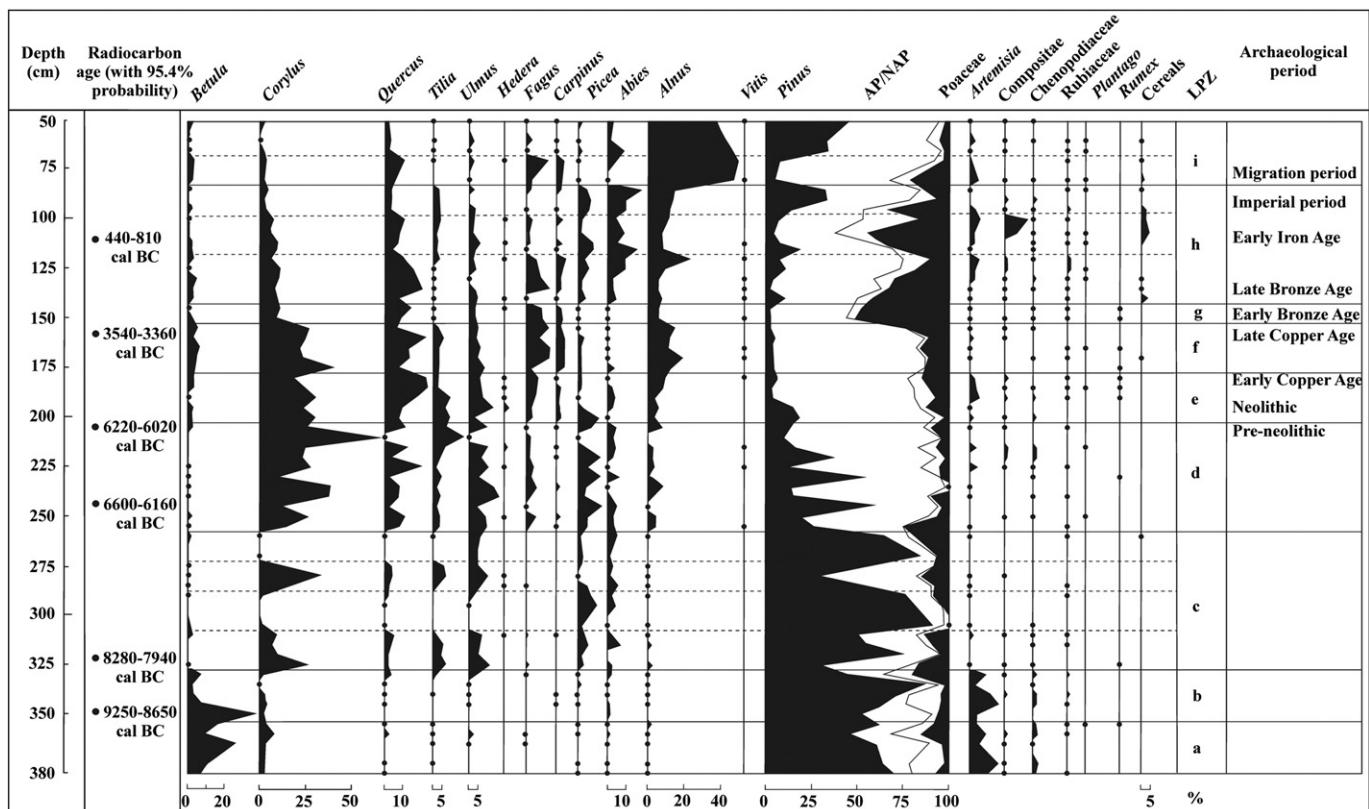

Fig. 5. Pollen analytical results of Zalavár (adopted and modified after Juhász, 2007).

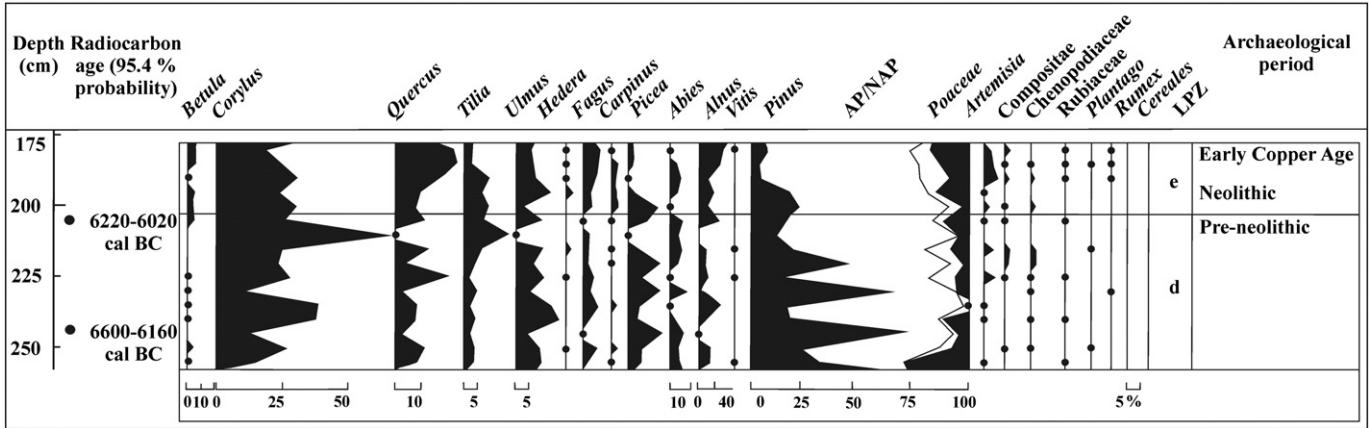

Fig. 6. Pollen analytical results of Zalavár with Local Pollen Zones d and e (adopted and modified after Juhász, 2007).

archaeological material. Moreover, she did not find significant differences in the fragmentation of *Quercus*, *Ulmus* and *Alnus* (Chabal, 1992). Vertical movements that cause the mixing of archaeological levels was not observable, however we can not exclude bioturbation.

#### 6.4. Review of *Fagus* colonisation into the study area in the light of the new results

*Fagus* charcoals are very important since their local presence indicate that *Fagus* trees existed in the region already in the Neolithic (Sümegi et al., 2011b). After Lang (1994) the spread of *Fagus* into Central Europe coincided with the Neolithic. In the study area *Fagus* charcoals are present from the Middle to the Late Neolithic and the pollen ratio of *Fagus* increase continuously from the 7th millennium BC and has a high significance. Hungarian palynologists (Juhász, 2002; Magyari, 2001) explain the time transgressional development of the pollen horizon of both species in the Carpathian Basin with migration processes. Furthermore both Hungarian palynologists (Juhász, 2002; Magyari, 2001) originate

the *Fagus* forests of the Carpathian Basin from the *Fagus* refugium of Slovenia, meaning that the origin of *Fagus* forests in Transdanubia, the North Hungarian Range and the Great Hungarian Plain resulted from this single Slovenian refugium. This one-centred beech colonisation model could be refused almost in the first moment it appeared by the radiocarbon dating of late glacial and Early Holocene pollen data of the Lake Balaton and Nagybákkány (Sümegi, 2005, 2007a; Jakab et al., 2009; Sümegi et al., 2009) and also by the late glacial Rejtek (Sümegi, 2007a) and Early Holocene Great Hungarian Plain (at Bátorliget) beech charcoal data (Sümegi, 2004b), both with radiocarbon dating (Fig. 7). The appearance of *Fagus* (and *Carpinus*) pollen in the study area and in the section is much earlier than it could be expected by the beech colonisation model. These data are well-parallelled with the results of pollen analyses carried out in the Austrian side of the foreland of the Eastern Alps and in Burgenland (Drescher-Schneider, 2004). The refugium of beech at the end of the glacial period probably consisted of many diffused patches (Magri et al., 2006; Magri, 2008; Brus, 2010), starting at the foreland of the Alps in Slovenia through the foreland of the Eastern Alps, all the way to the southern foreland of the Transdanubian Mountain Range. Besides this

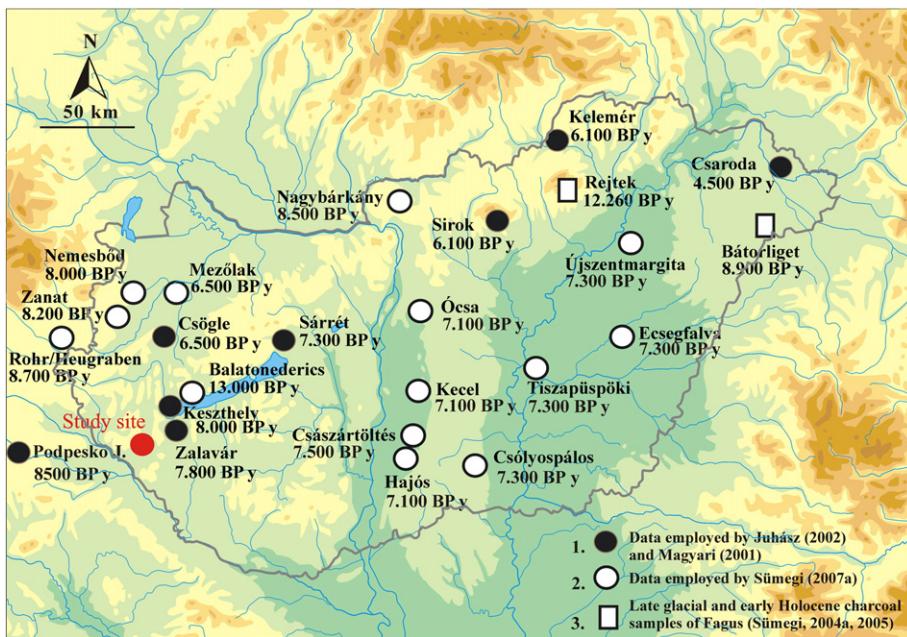

Fig. 7. Model of *Fagus* distribution based on *Fagus* pollen data (Gardner, 1998, 1999; Gardner and Willis, 1999; Magyari, 2001; Juhász, 2002) and own data supplemented by new radiocarbon dated pollen data, which followed the development of the distribution model (Drescher-Schneider, 2004; Jakab et al. 2004; Töröcsik, 2005, 2006; Juhász, 2005). Local presence of *Fagus* supplemented by charcoal samples (Stieber, 1964, 1967; Rudner et al. 2004; Sümegi, 2004a).

Praenoriticum and Praeillyricum refugium region another independent *Fagus* refugium may have existed in diffuse patches in the western part of the Carpathian Basin, in the North Hungarian Range and in the eastern side of the Munții Apuseni (Sümegi, 2004b, 2007a). The Middle Neolithic macroscopic charcoal fossils of *Fagus* may prove that an independent forest development characterised the western and southwestern part of Transdanubia and the existence of a *Fagus* refugium in the area. These data might support the existence of a “cryptic refugia” (Birks and Willis, 2008) in the area. It “refers to restricted refugia comprising areas with sheltered topography and buffered, stable local microclimates (Stewart and Lister, 2001) that are too localised or small to be detected by pollen analysis” (Birks and Willis, 2008).

### 6.5. Woodland reconstruction around the site

Relying upon the above mentioned facts (Shackleton and Prins, 1992; Chabal, 1997), previous statements (Jansen and Nelle, 2012) and the results of anthracological and palynological data we suppose that the anthracological data represents the wood taxa that were originally in the forest regarding arboreal species surrounding the study site. However, the selection of *Quercus* cannot be excluded. At the same time it was certainly the most abundant taxa in the forest around the Neolithic settlement.

The arboreal vegetation cover of the 1st and 2nd habitation phase cannot be reconstructed on the basis of anthracological analysis since only a little amount of charcoal turned up from Starčevo archaeological features (1st habitation phase) and none from the 2nd phase. However, the overburned charcoal material and ash filling of archaeological features of the 1st habitation phase (Starčevo culture) indicate human activity already during Early Neolithic. Moreover, palynological record also point to deforestation even during pre-Neolithic (Juhász, 2004). The rise of *Betula* and *Pinus* pollen and the cyclic change of *Corylus* (Juhász, 2004, 2007) indicate forest burning beforehand and the opening up the forest canopy. On the basis of pollen data a thermophilous *Quercus* dominated forest subsisted in the southwestern Transdanubian region.

Anthracological material from the Middle Neolithic gave appreciable results regarding arboreal vegetation. According to these results a deciduous thermophilous forest with *Quercus*, *Fagus*, *Ulmus*, and *Fraxinus* surrounded the former human settlement during the 3rd habitation phase of the Middle Neolithic, during the time period of the Sopot culture. Species of Pinaceae may exist on higher elevations and/or colder valleys.

During the time period of the 4th habitation phase (Lengyel culture) the thermophilous forest still existed around the settlement, indicating *Quercus* dominance mixed with *Acer*, *Fagus*, *Ulmus* and *Fraxinus*. On wet surfaces or riversides *Alnus* trees appeared.

The present forest associations such as Vicio oroboidi – Fagetum and *Fraxinus pannonicæ* – Ulmetum may have existed already during Middle and Late Neolithic. Nevertheless this latter was mixed with pine trees during the Middle Neolithic. Probably due to human impact such as deforestation, the decrease of moisture and the increase of temperature, the number of pine trees was reduced and during Middle Neolithic they disappeared from the forest assemblage. In fact, pine charred wood remains have not occurred from the later archaeological phase of the site. Probably the recent Querco-Ulmetum forest association developed as a result of human activity at the end of the Neolithic.

## 7. Conclusions

The importance of the archaeological site at Sormás-Török-földek lies in the fact that it provided a favoured unique opportunity to study the formation process of the Late Neolithic Lengyel culture. Besides the find material from the Sopot culture, one of the basic components of the Lengyel culture, the find material from the formative phase of the Lengyel culture was also found on the site. The formation process of the Lengyel culture could be studied through the comparisons of the find material and the settlement structures of both cultures.

The determination of the habitation phases and examination of the finds belonging to a given habitation phase made it clear that in habitation phase 3 (Sopot culture) and 4 (Lengyel culture) a continuous development may be estimated, in spite of the cultural change from Sopot culture to Lengyel culture. The whole existence of the site at Sormás-Török-földek indicates a long, peaceful development, which, based on radiocarbon data, lasted at least for 400 years. It is not known, what put an end to the existence of the early Lengyel settlement, but there are not any perceptible traces of violent occupation, invasion or destruction. The same may be supposed for the whole area and age that were examined (P. Barna, in press).

Besides the archaeological findings large quantity of charcoal samples were collected and identified to help to reconstruct the local former vegetation during the Neolithic. During the excavation, samples for anthracological analysis were collected. Sormás-Török-földek site is the first Neolithic site in Southwestern Transdanubia where anthracological analysis was carried out so it has a high importance in terms of the study site and the archaeological period. The result of the charcoal analyses was compared to pollen data of the Zalavár core in the Little Balaton region (Juhász, 2007; Fig. 3) to provide a more exact vegetation reconstruction. Although Zalavár does not lie in the immediate environment of the site, it is suitable for a regional comparison. Pollen data (Juhász, 2007) and other environment historical records (Willis et al., 1997, 1998; Magyari et al., 2002; Sümegi, 1998, 2004a,b, 2013; Sümegi et al., 2004) indicate that humans were present in the study area already before Early Neolithic.

The volume of the anthracological material is notable. The total sum of charred wood remains is 3693 pieces that cover 6 genera and one group of Pinaceae.

The site and the anthracological material are both absolute and relative chronological dated. Based on radiocarbon data the age of the Middle Neolithic (Sopot culture) and Late Neolithic (formative/Early Lengyel culture) settlements can be dated between 5050–4850 (68.2%); 5210–4830 (95.4%), 4790–4700 (68.2%); and 4840–4610 (95.4%) cal BC years (Table 2).

The charcoal assemblage indicates that deciduous thermophilous oak forest with *Fagus*, *Ulmus* and *Fraxinus* existed during Middle Neolithic (3rd habitation phase) (Table 5). *Fagus* and pine trees may have existed on higher hill slopes or in cooler valleys, while the *Quercus-Ulmus-Fraxinus* dominated forest occupied the lower areas. Pinaceae disappeared during or at the end of the Middle Neolithic and appeared again only in Keszthely Mountains during Bronze Age. Probably due to the warming up of climate, deforestation and the opening up of the forest canopy, the number of pine trees decreased during the Middle Neolithic. The auto-flammability of pines will be extreme through higher temperature (Payette, 1992) and the destructive work of wood-beetles will be more intensive in an open space. So human activity induce a local ecosystem transformation. As a consequence of it, the number of thermosensitive and humidity sensitive species was reduced. The creation of human settlements, roads, cultivated lands and grazing fields involve deforestation and the abovementioned effects. In addition, construction purposes demanded large quantity of wood. The anthracological and archaeological results indicate that different wood types were used for construction purposes such as *Quercus*, *Fagus* and Pinaceae. Furthermore, *Quercus* and *Fagus* were utilized as fuel wood as well, such as *Alnus*, *Fraxinus* and *Ulmus* (Table 6).

During the Late Neolithic (4th habitation phase) the thermophilous forest still existed around the settlement, indicating *Quercus* dominance mixed with *Acer*, *Fagus*, *Ulmus* and *Fraxinus*. On wet surfaces or riversides *Alnus* trees appeared. The archaeological data indicate the utilization of *Quercus*, *Acer* and *Alnus* as construction wood and fuel wood. *Ulmus* was used as fuel wood as it appeared only in a refuse pit. *Fraxinus* derive from one archaeological feature from the late phase of the 4th habitation phase and presumably was used for ritual activity (P. Barna, 2010). The structure of the archaeological feature, its charcoal

**Table 6**  
Summary of archaeological, anthracological, palynological and archeobotanical analysis.

Age	Archaeological period	Archaeological data from the site at Sormás-Török-földek			Charcoal	Pollen	Seeds/fruits
		Habitation phase	Sub-phase	Absolute chronology			
4900–4700 cal BC	Late Neolithic (the formative phase of the Lengyel culture)	4th habitation phase	4b	VERA-3538: 4780–4690 (68.2%); 4830–4610 (95.4%) cal BC No data	Quercus, Acer, Alnus, Fagus, Ulmus, Fraxinus	Quercus, Ulmus, Fagus, Alnus; Artemisia, Compositae, Chenopodiaceae, Rubiaceae, Plantago, Rumex	Triticum monococcum, Triticum spelta, Hordeum vulgare, Pisum sativum, Lens culinaris, Linum usitatissimum, Gramineae cultae, Chenopodium album, Sambucus racemosa, Bromus secalinus, Ononis spinosa
5000–4500 cal BC (Kálacz, 2007)	Middle and Late Neolithic transition (Sopot culture)	3rd habitation phase	4a	VERA-3539: 4790–4700 (68.2%); 4840–4610 (95.4%) cal BC;	Quercus, Fagus, Alnus, Ulmus, Fraxinus, Pinaceae	Quercus, Corylus, Tilia, Ulmus, Fagus, Alnus

			3a1	2nd habitation phase	No data	Quercus	
				1st habitation phase			
5500–5000 cal BC (Oross and Banffy, 2009)	Middle Neolithic (Linearband Pottery culture, LBK)						
6000/5900–5500 cal BC (Kálacz, 2007)	Early Neolithic (Starčevo culture)						

and ash filling, rich and unique findings may point to iterative ritual act of burning. However, the potential connections between the genera of wood (*Acer*, *Fraxinus* and *Quercus*) and the ritual use of the feature are still a question and the subject of further studies.

Besides charcoal fragments, pollen of herbaceous plants during Neolithic such as *Artemisia*, *Compositae* and *Chenopodiaceae* indicate human activity as well. Furthermore, seeds that turned up from the archaeological features indicate plant cultivation and animal husbandry. *T. monococcum*, *T. dicoccum*, *T. spelta* and *H. vulgare* seeds appeared. Further cultivars such as *P. sativum*, *L. culinaris* and *L. usitatissimum* seeds occurred (Sümegi, 2007b). Besides these, 287 pieces of fragments that belong to cultivated cereals (*G. cultae*) occurred. Weeds indicating cultivated lands, roads and settlements appeared, such as the presence of *C. album*, *S. racemosa* and *B. secalinus* support the cultivation of cereals. *O. spinosa* seeds point to animal husbandry, so besides plant cultivation, livestock farming was present in the Middle and Late Neolithic (Sümegi, 2007b).

The results of anthracological and palynological methods correlate well, some differences can be attributed to the different preservation of species, to burning qualities and to the regional nature of pollen which may hide distinct local vegetation characteristics.

The anthracological material originating from the Middle and Late Neolithic Sopot and Early Lengyel culture indicates unambiguous *Quercus* dominance. The wood of oak is valuable and workable hard wood that biological resistance is good due to its tannin content. It is durable and can be used for construction purposes and furniture making. Building remains found at the site suggest timber frame buildings with wattle and daub walls, amongst which we can find dwelling houses and buildings of other functions as well. Based on the more than 30 buildings, the enclosures and their related structure elements excavated on the site (palisades, wooden structures belonging to gates, wooden bridge), large-scale and wood-intensive construction activity can be concluded. So the dominance of *Quercus* in the charcoal assemblage most likely is the result of a conscious human selection, however its prevalence in the forest stand is unambiguous. This assumption is reinforced by the charcoal data indicating that except one sample where *Acer* was found, *Quercus* occurred from the objects of the enclosure.

The comparison shed light on the fact that while pollen data indicate *Tilia* and *Carpinus* presence in the region during Neolithic, they were not represented amongst charcoal remains derive form the archaeological site at Sormás-Török-földek. The wood of *Tilia* is soft and unsuitable for firewood (Kreuz, 1992), however at some places it occurred in large volumes (Jansen and Nelle, 2012). At the same time, it is easy to carve and ideal for furniture making and construction. *Carpinus* is an excellent raw for making tools as its wood is firm and hard. The absence of *Tilia* and *Carpinus* not necessarily indicate the selection of wood and as a consequence the avoidance of this two species in the forest stand. Due to the regional character of pollen and the distance between the archaeological site and the core location the lack of *Tilia* and *Carpinus* rather seems to indicate that they were not represented in the forests around the site. Our analysis and conclusions may be more accurate if a core closer to the study site could be performed.

The presence of *Fagus* charcoal is very important since their on-site remains indicate that *Fagus* trees existed in the region already in the Middle Neolithic that is very important regarding *Fagus* migration processes. Radiocarbon dated pollen and charcoal data from Hungarian sites (Sümegi, 2004b, 2005, 2007a; Jakab et al., 2009; Sümegi et al., 2009) indicate that the refugium of *Fagus* at the end of the glacial period probably consisted of many diffused patches (Magri et al., 2006; Magri, 2008; Brus, 2010) in the western part of the Carpathian Basin, in the North Hungarian Range and in the eastern side of the Munții Apuseni in Romania (Sümegi, 2004b,a).

It can be stated that the anthracological analysis of Sormás-Török-földek enabled a more accurate vegetation reconstruction for the study site by the comparison to previously known pollen analytical

data and added extra information regarding the local vegetation and wood utilization for the Middle and Late Neolithic.

## Acknowledgment

We express our gratitude to the excavators and workers of Sormás-Török-földek and Sormás-Mántai-dűlő for the obtained archaeological, macrobotanical and anthracological material and Dr. Nándor Kalicz (Archaeological Institute of the Hungarian Academy of Sciences) for his indispensable help during processing the archaeological material of the site. Pál Sümegi's research was supported by the European Union and the State of Hungary, co-financed by the European Social Fund in the framework of TÁMOP-4.2.4.A/2-11/1-2012-0001 'National Excellence Program'.
