Abstract. PTFE-metal composites are promising candidates for use as sensor materials. In present study PTFE-Au composite layers were deposited by alternated ablation of pressed Teflon pellets and gold plates with focused beam of an ArF excimer laser at 6 J/cm² fluence, while keeping the substrate at 150 °C temperature. The morphology and chemical composition of the ~3–4 μm average thickness layers was studied by electron microscopy and energy dispersive X-ray spectroscopy. The layers were mainly formed of PTFE grains and clusters which are covered by a conductive Au film. For testing the applicability of such layers as sensing electrodes, composite layers were prepared on one of the two neighbouring electrode of a printed circuit board. Cholesterol and glucose solutions were prepared using 0.1M NaOH solvent containing 10% Triton X-100 surfactant. The electrodes were immersed in the solutions and voltage between the electrodes was measured while a constant current was drawn through the sample. The influence of the analyte concentration on the power spectral density of the voltage fluctuation was studied.

1 Introduction

Due to the good mechanical, thermal and chemical stability polytetrafluoroethylene (PTFE) is a promising candidate for sensor preparation where its role can be either the immobilization of the component responsible for the sensing or even the participation in the sensing mechanisms when detecting humidity [1], SO₂ [2,3], O₂, CO₂ [4] or other gases [5,6]. The pulsed laser deposition (PLD) of PTFE thin layers is a thoroughly studied research field, the method allows the deposition of stoichiometric thin films with morphology ranging from compact to sponge-like structure [7–9]. The electrical and wetting properties can be tuned by addition of metals. Recent studies showed that PTFE/silver composite structures deposited by PLD using PTFE/Ag targets have a rough morphology with increased specific surface attributed to the deposition of PTFE grains and show improved conductive and wetting properties due to the Ag content [10].

In the last few years several attempts have been made for fabrication of non-enzymatic sensors for the detection clinically important analytes, as glucose [11,12], cholesterol [13,14] or urea [15]. These researches are motivated by the fact that, although the amperometric and potentiometric detectors based on incorporation of enzymes into the active electrodes [16–19] show good selectivity, the enzyme immobilization process is the most difficult step of the production process. The non-enzymatic sensors are

based on conductive electrodes with high specific surface and charges involved in electrocatalytic process are detected by amperometric measurement methods. While classical detection techniques are based on the measurement of the time-averaged value of the sensor signal, in some cases the existence of “fingerprints” of the analytes [20–22] in the low amplitude time-varying components of the signal were also demonstrated. This detection method is called fluctuation-enhanced sensing (FES). In a recent work the PTFE/Ag composite layer covered electrodes were immersed in cholesterol solution and the voltage fluctuation was measured while driving a constant current through the electrodes. It was found that power spectral density of the “noise” depended on the cholesterol concentration; however a quick aging of the electrodes due to the silver oxidation was observed [23].

In this work we present our results on the pulsed laser deposition of PTFE/gold composite layers onto electrodes of printed circuit boards and their behavior in fluctuation enhanced sensing measurements is monitored when immersed in solutions of cholesterol and glucose and their mixture.

2 Experimental

2.1 Thin film deposition

Composite layers formed of PTFE and gold were prepared by pulsed laser deposition onto one electrode of a printed

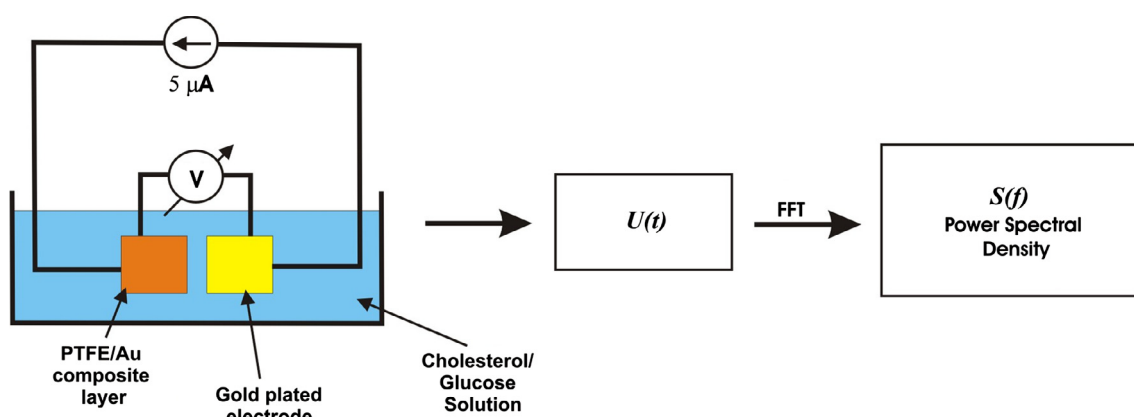

Fig. 1. Measurement procedure for the fluctuation-enhanced sensing.

Fig. 2. Electron microscopic image of the rough composite layer covered electrode (a) and elemental distribution on the same area for F (b) and Au (c).

54 circuit sample board containing a pair of $2 \times 2 \text{ mm}^2$ gold
 55 plated electrodes with 1 mm separation distance as pre-
 56 sented in detail earlier in reference [23]. The disk-shaped
 57 target was composed of two halves of disks: one of bulk
 58 Au and one of pressed PTFE powder. The experimental
 59 conditions were chosen based on the results of our ear-
 60 lier studies [9,10] as to assure degradation-free transfer of
 61 PTFE and appropriate mixing of Teflon and metal in
 62 order to obtain a rough surface conductive composite
 63 layer. The continuously rotated target was ablated with
 64 5000 pulses of an ArF excimer laser ($\lambda = 193 \text{ nm}$,
 65 FWHM = 20 ns) focused onto a 0.8 mm^2 area while
 66 the applied fluence was 6 J/cm^2 . During the deposition
 67 the sample board facing the target at 4 cm distance was
 68 kept at $150 \text{ }^\circ\text{C}$ temperature. The morphology and the
 69 elemental distribution of the prepared layers were studied
 70 with a Hitachi S4700 scanning electron microscope (SEM)
 71 equipped with a Röntec QuanTax energy-dispersive X-ray
 72 spectrometer (EDX).

73 2.2 PTFE/Au composite layers as sensor electrodes

74 A 0.1M NaOH solvent containing 10% Triton X-100 sur-
 75 factant was used to prepare solutions of 2 and 5 mM
 76 cholesterol, 5 and 15 mM glucose and their mixtures.
 77 The fluctuation based sensing measurements were per-
 78 formed as follows: the sample board was immersed ver-
 79 tically into the solutions until the two electrodes became

fully covered (Fig. 1). A constant current of $5 \mu\text{A}$ was
 drawn through the circuit and the $U(t)$ voltage between
 the two electrodes was measured with 38 nV resolution
 at a sampling rate of 4000 Hz for a period of 15 s.
 The $S(f)$ power spectral density of the voltage fluctuation
 was obtained by fast Fourier transform (FFT) in LabView
 software environment. The signal was divided in 30 pcs.
 of 0.5 s segments and their FFT spectra were averaged.
 Reference measurements on untreated electrodes were also
 carried out.

3 Results

3.1 Thin film characterization

As the electron microscopic image in Figure 2a shows, the
 layers have a rough surface, since the PTFE ($-\text{[C}_2\text{F}_4\text{]}_n-$)
 is mainly transferred in form of grains and larger clus-
 ters, only a minor part can be originated from repoly-
 merization from larger polymer chain fragments. Elemental
 microanalysis was realized by EDX and the results proved
 that the gold is more uniformly distributed over the
 deposited area. More detailed previous studies showed
 that the darker areas on the image showing the elemental
 map of the gold (Fig. 2c) can be attributed to the shield-
 ing effect of the PTFE grains, since their size is larger
 than the $\sim 1 \mu\text{m}$ detection depth of the EDX. As the
 alternate ablation of the two components results in the

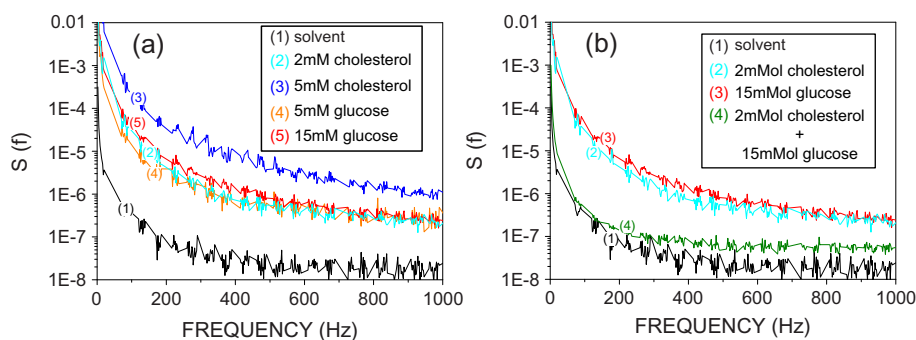

Fig. 3. Spectra of the voltage fluctuation for different solution types when using composite layer covered electrode (a) and comparison of the spectra recorded with a two component solution to the corresponding single component spectra (b).

105 covering/mixing of the Teflon structures with the metal,
 106 the layers became conductive; moreover the wettability is
 107 also increased as compared to pure PTFE. These proper-
 108 ties of the layers assure an increased contact area when
 109 the electrode is immersed in the solution, as compared to
 110 the original, uncovered electrodes.

111 3.2 Fluctuation-enhanced sensing

112 For voltage fluctuation measurements each solution was
 113 tested with a new sample board. $S(f)$ power spectral den-
 114 sity function was obtained in 0–2 kHz frequency range
 115 with 2 Hz resolution according to the sampling rate and
 116 the length of the $U(t)$ signal used for FFT. In most cases
 117 the harmonics of the 50 Hz grid frequency appeared in
 118 the spectra, which were cut off. In case of untreated
 119 electrodes the analyte and its concentration did not show
 120 observable influence on the obtained $S(f)$ spectra. In con-
 121 trast to this, there was a noticeable difference between the
 122 spectra obtained in presence of cholesterol and glucose
 123 solutions with different concentrations (Fig. 3a). In case
 124 of the conducting pure solvent the noise spectrum origi-
 125 nates from its characteristic resistance fluctuation, which
 126 is a general property of conductive elements in electronics.
 127 In case of cholesterol and glucose solution the charge
 128 transfer related to their electrocatalytic reaction at the
 129 surface of the rough electrode also contributes to the
 130 detected noise. This indicates that due to their rough
 131 surface such composite layers may serve as active elec-
 132 trodes in non-enzymatic electrocatalytic sensors. In case
 133 of real measurements the interference between the differ-
 134 ent analytes being present in monitored solution has to
 135 be taken into account. The Figure 3b shows an exam-
 136 ple spectrum for a solution containing both cholesterol
 137 and glucose as compared to appropriate single component
 138 solutions. Although we expected the spectra of the
 139 mixtures to be situated somewhere between those cor-
 140 responding to the single component solutions, there is
 141 no straightforward relationship between the correspond-
 142 ing spectra.

143 A quantitative comparison of the spectra was real-
 144 ized by principal component analysis (PCA). Since value

Fig. 4. Result of PCA analysis of the voltage fluctuation spectra recorded for different solutions represented in PC-1 - PC-2 plane. The arrows indicate the tendency for increasing concentrations of single component solutions.

144 ranges of the $S(f)$ functions cover several orders of
 145 magnitudes, their logarithm was calculated and then fit-
 146 ted with a third order exponential decay function. Thus
 147 smooth curves following the tendencies of the spectral
 148 functions were obtained and their 2–100 Hz frequency
 149 range was submitted to PCA analysis. Figure 4 shows the
 150 plotted values of the first two components of the result-
 151 ing scores matrix (PC-1 vs. PC-2). The data points indicate
 152 that even if there is a tendency when varying the concen-
 153 trations of cholesterol and glucose solutions, one cannot
 154 find a connection between the position of the data points
 155 for the mixtures and the concentration of the components.
 156 PCA can be used also for evaluation of infrared absorp-
 157 tion spectra of multicomponent samples. Supposing no
 158 interaction between the components, the total absorp-
 159 tance is the summarized absorbance of the individual con-
 160 stituents. In case of a three component sample, perform-
 161 ing a PCA analysis on IR spectra recorded for different mix-
 162 tures and plotting the results in plane a ternary graph-
 163 like triangular point distribution can be obtained with

Fig. 5. Averaged spectra recorded at the beginning and at the end of 10 min aging test.

163 points corresponding to the three pure samples on the
 164 corners of the triangle, as demonstrated in by Bacci et al.
 165 (calcareous samples [24]) and Norgaart et al. (sucrose
 166 and its components [25]). Obviously, in case of four con-
 167 stituents the first three PC components of the score
 168 matrix have to be plotted in a 3D coordinate system, etc.
 169 In our case the solution can be considered as a three com-
 170 ponent sample formed of solvent, glucose and cholesterol.
 171 When either the cholesterol or glucose was dissolved, the
 172 linear shift in PC-1 - PC-2 plane of the data points as
 173 the function of concentration was visible in our case, too.
 174 The behavior of the cholesterol-glucose mixtures was
 175 different from the above mentioned case of IR spectral
 176 analysis, which can be partly attributed to the lack of
 177 component-specific peaks in the recorded noise spectra
 178 and partly to the fact that the presence of one solved com-
 179 ponent influences the interaction of the electric charges
 180 with the other solved component resulting in a non-
 181 additive aspect of the noise spectra. This suggests that
 182 in presented experimental parameters the fluctuation
 183 enhanced sensing accompanied with principal component
 184 analysis is not a practicable way for multicomponent
 185 analysis in liquid phase. A possible solution could be the
 186 monitoring of the noise when altering the driving current
 187 (and consequently the constant component of the mea-
 188 sured voltage), since the electrocatalytic process of glucose
 189 and cholesterol is voltage dependent.

190 In an earlier study a quick degradation of the silver
 191 based composite electrodes (probably caused by oxida-
 192 tion) was observed during similar experiments and only
 193 the spectra recorded in the first 15 s could be used for eval-
 194 uation. Therefore the stability of the PTFE/gold compos-
 195 ite layers and temporal behavior of the recorded spectra
 196 were also tested. There was no observable discoloration
 197 of the electrodes even after 10 min continuously running
 198 experiment. Figure 5 shows an example on the noise
 199 spectral stability recorded in case of 5 mM cholesterol
 200 solution.

4 Summary

202 Pulsed laser deposition method was used to prepare
 203 conducting PTFE-gold composite layers for sensor elec-
 204 trode purposes. The increased specific surface of the layers
 205 increased the sensitivity of the electrodes as compared to
 206 the original smooth gold plating, when measuring voltage
 207 fluctuations in presence of cholesterol and glucose
 208 solutions. While the earlier studied PTFE-silver compos-
 209 ite electrodes showed a fast aging due to the oxidation of
 210 the silver, the use of gold as conducting element resulted
 211 in significant increase in stability. Although there is obvi-
 212 ous influence of the concentration on the recorded spectra,
 213 in case of two component solution the separation of the
 214 components' effect is not straightforward. Similar difficul-
 215 ties were encountered in multicomponent gas sensing with
 216 FES method. Further studies on optimization of measur-
 217 ing parameters (electric current value, sampling rate, etc.)
 218 and data processing methods are needed for enhancing the
 219 cross-selectivity of the method.
