Knowledge explosion for monogenic skin diseases

During the past few decades, the investigative technologies of molecular biology - especially sequencing - underwent huge advances, leading to the sequencing of the entire human genome, as well as the identification of several candidate genes and the causative genetic variations that are responsible for monogenic skin diseases. These advances provided a solid basis for subsequent studies elucidating mechanisms of monogenic skin diseases and improving our understanding of common skin diseases. Furthermore, these discoveries also contributed to the development of novel therapeutic modalities for monogenic skin diseases. In this review, we have used the disease spectrum caused by mutations in the CYLD gene - Brooke-Spiegler syndrome, familial cylindromatosis and multiple familial trichoepithelioma type 1 - as a model for demonstrating the knowledge explosion for this group of diseases.

Key words: Familial trichoepitheliomatosis; Familial cylindromatosis; Brooke-Spiegler syndrome; Monogenic skin diseases

INTRODUCTION

From ancient times to the present, the basic approach for diagnosing skin diseases has been to classify the diseases according to their visible signs and symptoms. This approach highlights that dermatology is still a highly morphology-orientated specialty. The end of the 18th century saw great breakthroughs in dermatology: the first comprehensive textbook of modern dermatology was published in 1799 by Francesco Bianchi and the first great school of dermatology was established in Paris in 1801. Since that time, the desire to understand the nature of observed skin lesions constantly drives the development of dermatology and the incorporation of novel investigative methods into its everyday practice.

Among these methods, dermatohistopathology has had the highest impact on the diagnosis of skin diseases. Although the microscope was invented by Anton van Leeuwenhoek as early as 1673, the first standardized and classified nomenclature of dyes and stains was prepared only in 1924. Since that time, enzyme histochemistry, electron microscopy, polarizing microscopy, immunohistochemistry and in vivo confocal microscopy have all become diagnostic tools in dermatohistopathology and have been integrated into everyday dermatology practices. In recent decades, developments in the investigative fields of clinical genetics and genomics have further accelerated our knowledge about skin diseases.

Breeding agricultural plants and animals characterized the pre-Mendel era of genetics. After Gregor Mendel established the basic rules of heredity in the nineteenth century, several major discoveries, such as the identification of DNA as the material encoding inheritable information, of the genetic code and of the mechanisms of gene expression, have initiated the era of molecular genetics. Very recently, the enormous technical development of sequencing methods and platforms has resulted in large-scale genomic projects, which produce amounts of data that were unimaginable a few decades ago.

These discoveries and techniques have been used to identify several normal genetic variations, as well as candidate genes and their disease-causing mutations, accelerating the elucidation of the genetic background of several monogenic skin diseases. In this review, we present the knowledge explosion for monogenic skin diseases, using as an example the disease spectrum caused by mutations in the CYLD gene, which involves Brooke-Spiegler syndrome (BSS) (OMIM 605041), familial cylindromatosis (FC) (OMIM 132700) and multiple familial trichoepithelioma (MFT1) (OMIM 601606) (Table 1).

DISCUSSION

BSS is a rare monogenic skin disease characterized by the development of a wide variety of benign skin appendageal tumors, such as cylindromas, trichoepitheliomas and/or spiradenomas. BSS was named after the two physicians who first reported these neoplasms in 1892 and 1899: Henry G Brooke and Eduard Spiegler, respectively. FC, which was originally considered a separate rare disease, is characterized by the development of cylindromas. FC was first reported in 1842 and 1899 by Henry Ancell and Eduard Spiegler, respectively. MFT1, which was also reported as another rare entity, is characterized by the development of trichoepitheliomas and was first reported in 1892 by Brooke and Fordyce.

Comparing the clinical features of these tumors, cylindromas are benign, skin-colored tumors usually present as multiple tuber-like protrusions on the scalp, trichoepitheliomas are small, benign, skin-colored tumors, typically located at the center of the face, and spiradenomas are purple, benign, nodular tumors, usually located on the trunk or limbs. The histological characteristics of cylindromas are dermal nodules of epithelial cells lined by membrane-like basement material and arranged in a “jigsaw puzzle” pattern, of trichoepitheliomas are dermal nodules of basaloid cells with peripheral palisades arranged in nests or cribriform patterns and of spiradenomas are dermal nodules comprised of large light-colored epithelial cells with abundant cytoplasm at the center and small darker epithelial cells at the periphery. Hybrid tumors can also occur, such as spiradenocylindromas, which exhibit the characteristics of both cylindromas and spiradenomas.

The candidate gene for BSS was first mapped to chromosome 16q12-q13 in 2000, and the causative CYLD gene and its first pathogenic mutation was identified in an affected German pedigree in 2002. The candidate gene for FC was first mapped to chromosome 16q12-q13 in 1995, however, the causative CYLD gene and the first 21 pathogenic mutations were identified as late as 2000. It was first suggested in 1995 that MFT1 and FC may be caused by the dysfunction of the same gene, since both type of tumors can occur in the same patient or in different patients within a single family. The causative gene for MFT1 was identified as CYLD and the first pathogenic mutation was detected in an affected Turkish family in 2003.

These clinical variants - BSS, FC and MFT1 - were originally described as distinct clinical entities. However, due to their overlapping clinical symptoms and their manifestation within the same family, they are currently considered as part of a phenotypic spectrum of the same entity. This hypothesis is supported by genetic evidence: several mutations - the c.1112C/A p.S371X, the c.2272C/T p.R936X nonsense mutations (Table 2) - have been reported worldwide (Figure 1). The majority (82%) of CYLD mutations identified to date

Knowledge explosion for monogenic skin diseases

It is interesting to note that, although the CYLD protein is expressed in a wide range of human tissues, the reason why dysfunction manifests only in skin symptoms is still unclear[30,31]. Moreover, patients carrying the same mutation from different mutational events often exhibit extreme differences in their clinical and histological manifestations[32]. These differences might be the consequences of yet unknown genetic, environmental and/or lifestyle factors that modify the development of the phenotype. Further
studies are needed to elucidate the putative factors that are responsible for the observed late onset of the symptoms, for the development of only skin manifestations and for the great variation in phenotypes and histological findings.

To date, no causative therapy is available for BSS. However, recent gene expression studies demonstrated that tumors with somatic CYLD mutation have impaired TRK signaling and treatment with a small TRK-inhibiting molecule, lestaurtinib, can reduce colony formation and proliferation of tumor cells with somatic CYLD mutation[18]. These data may have huge clinical significance, since lestaurtinib treatment might be a novel therapeutic modality for patients suffering from symptoms caused by germline CYLD mutations.

CONCLUSION

Although dermatology and genetics are considered separate disciplines, the combination of these two fields has already resulted in enormous improvement in the understanding of monogenic skin diseases, such as the skin-disease spectrum caused by mutations in the CYLD gene. Genetic studies have proved that BSS, FC and MFT1, which were originally considered different entities, result from mutations of the same gene. Moreover, mutations of the CYLD gene have been reported in patients presenting all clinical variants. Genetic screening and the identification of the disease-causing mutation have already been of great significance for family planning in prenatal and preimplantation diagnosis. Furthermore, molecular biological investigation demonstrated that all known CYLD mutations led to decreased activity of the encoded CYLD deubiquitinase enzyme and, thus, influence several signal transduction pathways. Currently, only symptomatic surgical treatment is available for patients with BSS, FC or MFT1. Gene expression studies of solid tumors carrying the CYLD mutation identified modifications in the TRK signaling pathway and raised the possibility that treatment with lestaurtinib could be effective than the symptomatic treatments currently available for the disease. Currently, only symptomatic surgical treatment is available for patients with BSS, FC or MFT1. Gene expression studies of solid tumors carrying the CYLD mutation identified modifications in the TRK signaling pathway and raised the possibility that treatment with lestaurtinib could be effective than the symptomatic treatments currently available for patients with BSS, FC and MFT1 variants.
