

Mixed Invasive Apocrine Papillary/Micropapillary Carcinoma of the Breast – Another Brick in the Triple Negative Wall

ABSTRACT

Pure invasive papillary carcinoma (IPC) is a rare subtype of breast carcinoma with good prognosis compared to classical invasive breast carcinoma (IBC) of no special type. The majority of IPC are estrogen receptor and progesterone receptor (ER/PR) positive and Her2-negative (luminal A-like). We report the case of a 72-year-old woman who was referred to the Senology Clinic for a routine work-up following surgery for an intraductal papilloma. The core needle biopsy (CNB) showed a lesion predominantly composed of irregular papillae and micropapillae with apocrine epithelial cells of low-to-intermediate nuclear grade, without a myoepithelial cell (ME) layer within the papillae and at the periphery, as demonstrated with multiple immunostains. The diagnosis of apocrine papillary lesion of uncertain malignant potential was made. The subsequent lumpectomy showed an IBC with the same cyto-architectural features as the CNB. In addition, lymphovascular invasion and papillary/micropapillary apocrine in situ lesion were noted. Notably, the tumor was ER/PR and Her2 negative and strongly positive for androgen receptor. A final diagnosis of mixed apocrine papillary/micropapillary carcinoma with triple-negative status was made.

To the best of our knowledge, this is the first report of an IBC with these features. Breast pathologists should be aware of this entity when dealing with CNB specimens characterized by a complex papillary lesion with apocrine atypia that lacks a ME layer on multiple immunostains. These lesions should be classified at least as of uncertain malignant potential based on the cyto-architectural features prompting a surgery for removal.

Keywords: breast carcinoma; papillary; micropapillary; apocrine; triple-negative; histological variant.

INTRODUCTION

The 2019 World Health Organization (WHO) Classification of Breast Tumours defines pure invasive papillary carcinoma (IPC) as an infiltrating carcinoma completely composed of fibrovascular cores covered by neoplastic epithelium.^{1,2} IPC may present as pure invasive forms, or with an associated invasive breast cancer (IBC) of no special type (NST), and may be associated with papillary ductal carcinoma in situ (DCIS).³ Pure IPC is extremely rare, representing approximately 0,5% of all invasive breast cancers (IBC).⁴

Liu et al. published the first large clinicopathological cohort of IPC (284 cases) in 2013, and found that the incidences of local recurrence, distant metastasis and cancer related death were relatively low with a significantly more favorable prognosis than IBC-NST.³ In 2016, a SEER population-based study reported the largest clinicopathological cohort (524 cases).⁵ A lower grade, a smaller tumor size, reduced lymph node involvement, earlier stages, higher hormone receptor expression and lower Her2 amplification rates were found for IPC compared to IBC-NST.⁵

Rare variants of IPC showing a more aggressive behavior have also been described, such as cases of triple-negative IPC,³ a small case series of tubulopapillary IBC⁶ and a case of triple-negative apocrine IPC.⁷ To our knowledge, no cases of mixed apocrine papillary/micropapillary IBC have been described to date.

We report a unique case of a triple-negative breast carcinoma with mixed papillary/micropapillary architecture and apocrine features. A detailed histopathological comparison between the core needle biopsy (CNB) sample and the lumpectomy specimen (with sentinel lymph node biopsy) is also provided.

MATERIALS AND METHODS

Clinical Findings

A 72-year old woman was referred to the Senology Clinic for a routine workup after surgical treatment for an intraductal papilloma diagnosed four years before, in the same breast and in the same quadrant. Breast ultrasonography revealed the presence of an irregular 15 mm solid mass with regular contours in the left breast. The patient underwent CNB and subsequently complete excision of the lesion with lumpectomy and sentinel lymph node biopsy

Sample and Immunohistochemistry

Tissue samples obtained were fixed in 10% formalin and embedded in paraffin. Paraffin-embedded tissue blocks were cut into 2 to 3 micrometer sections and stained with hematoxylin-eosin (H&E).

Immunohistochemistry (IHC) was performed with the following antibodies on specifically serial sections: CK5, clone XM26 (Leica), 1:600 dilution; p63, clone 7JUL (Leica), 1:50 dilution; S-100, rabbit polyclonal serum (Leica), 1:300 dilution; calponin, clone 26AII (Leica), Ready To Use; smooth muscle actin (SMA), clone asm-I (Leica), 1:50 dilution; Ki-67, clone MM1 (Leica), Ready to Use; estrogen receptor (ER), clone 6F11 (Leica), 1:100 dilution; progesteron receptor (PR), clone

16 (Leica), 1:100 dilution; androgen receptor (AR), clone AR441 (Dako), 1:400 dilution; GCDP-15, clone 23A3 (Leica), 1:400 dilution; Her2, clone Her2 (Leica), Ready to Use; D240, clone D240 (Biocare), Ready to Use; in-house assembled calponin/p63 and CK5/p63 multiple stains were also used.

Digital Image Analysis

The Aperio ScanScope CS slide scanner was used at x20 to digitize the Ki67 stained slide and to evaluate the Ki67 proliferation rate with the automatic nuclear segmentation method performed by the nuclear algorithm of the Spectrum Webscope platform.

RESULTS

Pathological and Immunophenotypical Findings on Core Needle Biopsy

Four bioptic samples were obtained with ultrasound-guided CNB. H&E sections demonstrated a lesion mainly composed of irregular papillae with fibrovascular cores (Figure 1A-B), covered by epithelial cells often showing micropapillary outgrowths (without fibrovascular cores, like in micropapillary DCIS or micropapillary ovarian cancers) and sometimes displaying cribriform lumens. The neoplastic epithelium was characterized by marked apocrine features and low to intermediate nuclear grade (Figure 1C). Less than 10% of the lesion showed a micropapillary and solid architecture without a papillary background structure, always with apocrine features. No clearly infiltrative foci were noted, although some were highly suspicious. Necrosis was absent. Mitoses were rare. Myoepithelial (ME) cells were not detected on the H&E stained slides and multiple stains for ME markers (CK5, S-100, p63, SMA calponin, calponin/p63 and CK5/p63) were completely negative (Figure 1D). As the rare lack of myoepithelium in benign apocrine proliferations has been described, a final diagnosis of papillary lesion of uncertain malignant potential was made with a B3 classification according to Ellis⁸ and a complete removal of the lesion has been strongly indicated.

Pathological and Immunophenotypical Findings of the Lumpectomy

The patient underwent lumpectomy with sentinel lymph node biopsy. At gross examination, the breast mass was solid, well-circumscribed with lobulated margins and whitish with a diameter of approximately 1.5 centimeter. H&E sections showed that the lesion was surrounded by a thin and discontinuous pseudocapsule. The invasive tumor within this was composed of either anastomosing and branching papillary fronds with central fibrovascular cores. Coalescing luminal epithelial cells and sometimes cribriform structures (Figure 2A-B) or eye-catching micropapillary outgrowths or typical inside-out patterned cell groups were highlighted. At some places, the fibrovascular bands were clearly cores of papillary structures. At other places, it was difficult to decide whether they were septa between nests or cores of papillae with dissociated epithelium (Figure 2C). The micropapillary outgrowths and cribriform secondary lumens of the apocrine epithelium, were also present in this specimen. The exact proportion where the structure was clearly papillary was difficult to estimate, but was obviously greater than 10% and around 50% by two

observers and around 90% by two other observers. The neoplastic cells showed apocrine atypia with a 2 to 3-fold nuclear enlargement, hyperchromasia and prominent/multiple nucleoli (Figure 2C). Necrosis was absent and the mitotic activity was low (5 mitoses per 10 high power fields). An Elston-Ellis grade 2 was assigned.⁸ Several foci of lymphovascular invasion into and beyond the pseudocapsule were noted (Figure 2D). In addition, foci of cribriform and papillary/micropapillary DCIS, the latter with apocrine atypia, were noted beyond the pseudocapsule in the surrounding breast tissue (Figure 2E).

On IHC, the calponin/p63 and the CK5/p63 multiplex stains showed a complete absence of the ME cell layer around the invasive component and its presence around the DCIS component. Ki-67 proliferation rate evaluated with digital nuclear image analysis was 5.5%. The negative expression of ER, PR and Her2 (Figure 2F-G) classified biologically the invasive component as triple-negative, while diffuse positive expression of AR (Figure 2H) and GCDFP-15 showed the apocrine nature of both the invasive and in situ papillary/micropapillary components.

The final diagnosis was “mixed invasive apocrine papillary/micropapillary carcinoma associated with foci of cribriform and apocrine papillary/micropapillary DCIS. The pathological TNM stage was: pT1c pN0(sn) M0, i.e. anatomical stage IA and prognostic stage IB.

Follow-up and Treatment

No recurrence of the disease has been observed at the 6-month-follow-up. After surgery, the patient received a whole breast irradiation (WBI) consisting of 16 daily fractions of 265 cGy to a total dose of 4,24 Gy. No adjuvant chemotherapy was given because of an anxiety-depressive syndrome.

DISCUSSION

Pure IPC represents approximately 0,5% of IBC.³ Most commonly it is diagnosed ~~seen~~ in postmenopausal females and rarely in males.³ Mixed papillary carcinomas with less than 90% obvious papillary structure are also rare. IPC usually have low-grade nuclei, low mitotic activity, are ER and PR positive and Her2 negative.^{3,4} They carry a favorable prognosis compared to IBC-NST.^{3,4} To our knowledge, apocrine invasive micropapillary has not been described before. We report a unique case of mixed apocrine IPC with micropapillary features, which may represent a distinct subtype of IPC, micropapillary carcinoma or apocrine carcinoma and a potential diagnostic pitfall on CNB.

Triple negative IPC represent a subset of IPC (about 19% according to Liu et al.)³ and apocrine differentiation is extremely rare. The only IPC with apocrine features, that was reported in the literature, has been described by Terzi et al. and showed high nuclear grade, high mitotic activity, abundant necrosis and remarkable lympho-plasmacytic stromal infiltrate; no lymphovascular invasion was noted.⁷

At variance from that case, ours displayed a low-to-intermediate nuclear grade, a low mitotic activity and neither stromal lympho-plasmacytic infiltrate, nor necrosis. It was also characterized by lymphovascular invasion within and beyond the tumor border and in situ disease in the surrounding breast tissue composed of cribriform and micropapillary/papillary DCIS, the latter with apocrine features.

Pure special type carcinomas require at least 90% of the tumor to be composed of the characteristic features. The current WHO classification groups breast cancers

according to several features, thus it allows for dual classifications.² This invasive carcinoma fulfils the 90% criterion of pure apocrine carcinoma, and on structural grounds, it is partly papillary and micropapillary and can be classified as mixed papillary and micropapillary. The excessive lymphovascular invasion is explainable with this latter morphological pattern.

Our case provides additional evidence of the heterogeneity of triple-negative breast cancers the spectrum of which has more histotypes than what is expected on the basis of published works.⁹ Apocrine lesions, for many pathologists imply an ER and PR negative status by definition.^{10,11} Malignant apocrine tumors may be Her2-negative or positive, the tumor being triple-negative in the first setting. The apocrine subtype of triple-negative breast cancers is also recognized on the basis of gene-expression profiles.^{11,12}

The association between papillary lesions and apocrine changes represents a great challenge for breast pathologists. Papotti et al. first reported areas of apocrine differentiation in papillary breast carcinomas with and without invasion.¹³ Apocrine changes in papillomas may be extensive and in some cases, can be difficult to distinguish from low-grade DCIS.^{14,15} Apocrine differentiation may be prominent in papillary DCIS leading to classification as apocrine papillary DCIS.^{16,17} Eleven cases of apocrine encapsulated papillary carcinoma have been reported,¹⁸⁻²⁰ the latter published by Kovari et al. was associated with IBC-NST with apocrine features.²¹ Benign apocrine lesions lacking myoepithelium, including papillary lesions that may mimic papillary carcinomas were described by Cserni in 2008²² and in 2012²³, by Tramm et al. in 2011²⁴, as well as Ha et al. in 2018.²⁵

Papillary breast lesions that may show apocrine changes are summarized in table 1. To our knowledge, solid papillary carcinomas and tall cell carcinomas with reversed polarity with apocrine phenotype have not been described so far.

From a practical point of view, apocrine papillary lesions may represent a considerable exception to the general rule that the absence of ME cells in breast lesions is usually considered a hallmark to separate invasive from in situ and malignant from benign lesions. In fact, benign and non-invasive apocrine lesions may show a reduction and occasional complete loss of ME.²⁴ The same concept was highlighted by Cserni et al., who reported two cases of apocrine intracystic papillary proliferation devoid of ME cells stressing again that even a complete lack of myoepithelium should not be equated with a diagnosis of malignancy. Given the importance of ME cells, and given their sometimes unpredictable immunoprofile, it is important to use a combination of different immunohistochemical ME markers.²³

Combined immunostains, such as calponin/p63 and/or CK5/p63, may be useful in this context, especially as they may spare precious bioptic material in small CNB samples. From another side, well circumscribed papillary tumors, like encapsulated and solid papillary carcinomas, are staged as in situ carcinoma despite their lack of ME cells at the periphery of the structures involved.^{26,27}

Breast pathologists should be aware that ME cells may be absent in some benign apocrine papillary lesions and thus should interpret this finding in the light of the whole histopathological picture.

In our case, the CNB showing a complex apocrine papillary proliferation with low to moderate cytological atypia, lack of ME layer demonstrated on multiple immunostains and absence of clearly infiltrative foci, was a diagnostic challenge. It could have been over- or under-diagnosed as a malignant or a benign papillary apocrine proliferation, respectively. Therefore, we believe that these lesions should be reported as papillary lesion of uncertain malignant potential, or suspicious of malignancy requiring surgical excision.

FIGURE LEGENDS

Figure 1

Core needle biopsy (CNB). The lesion has a complex architecture composed by irregular papillae with fibrovascular cores and micropapillae, 5X, H&E (A), 10X, H&E (B). The irregular papillae and micropapillae are covered by cells with round nuclei with different size and shape, prominent nucleoli and marked apocrine features, 20X, H&E (C). Note the micropapillary projections seen on the high-power view (C). Absence of Calponin/p63 expression, 10X, IHC (D).

Figure 2

Lumpectomy specimen. Well circumscribed nodule surrounded by a thin and discontinuous pseudocapsule, 1X, H&E (A). Papillary configuration of the lesion with thin irregular papillae and fibrovascular fronds lined by neoplastic cells with apocrine atypia, 5X, H&E (B), 20X, H&E (C). Note the invasive micropapillary pattern reflected by the inside-out reverted polarity of the tumor cells (C). Multiple foci of invasion in small lymphatic channels, with the tumor emboli also displaying the reverted polarity of micropapillary carcinoma 10X, H&E (D). Multiple foci of papillary/micropapillary ductal carcinoma in situ (DCIS) with apocrine features in the surrounding breast tissue, 10X, H&E (E). Absence of nuclear expression of estrogen receptor (ER), 10X, IHC (F). Absence of membrane expression of HER2, 10X, IHC (G). Intense nuclear expression of androgen receptor (AR), 10X, IHC (F).
