### ***Abstract***

The Kiskunhalas-NE (KIHA-NE) fractured CH-reservoir is part of the structurally rather complex crystalline basement of the Great Hungarian Plain. In course of petrological and thermometric examinations various rock types of the investigated area have been classified and characterized. There are four basic lithological units in the area; in the lowest structural position orthogneiss is common, which according to its petrographic features is assumed to be identical to the orthogneiss body of the adjacent Jánoshalma (JH) basement high (metamorphic peak temperature  $T < 580^{\circ}\text{C}$  according to Zachar and M. Tóth, 2004). The next rock unit upward is the highly mylonitized variety of the orthogneiss bearing textural features suggest deformation in an extensional stress regime. In the higher section of the mylonite zone graphitic gneiss mylonite is characteristic, with a peak metamorphic  $T$  of  $410 \pm 45^{\circ}\text{C}$ . The lithology at the shallowest position of the area is a graphitic carbonate phyllite, with a  $T$  of  $375 \pm 15^{\circ}\text{C}$ . Estimation of the deformation temperature for both mylonitic rocks results approximately in  $T_{\text{def}} \sim 455^{\circ}\text{C}$ . All data together suggest that between the top (graphitic carbonate phyllite) and the bottom (orthogneiss) of the ideal rock column there is about  $200^{\circ}\text{C}$  peak metamorphic temperature deviation. The two extreme metamorphic blocks probably got juxtaposed along an extensional fault zone in the basement at approximately 15 km depth.

### **Introduction**

Crystalline basement of the Pannonian Basin in several places accumulates significant amount of hydrocarbon. Understanding of these fractured reservoirs is rather challenging because of the complicated structural evolution of the metamorphic complexes. As there is no surface outcrop in the region, metamorphic rock bodies can be examined only using the very limited number of borecore specimens. Previous studies of numerous hard rock reservoirs in the Pannonian Basin (Zachar and M. Tóth 2001, Schubert and M. Tóth 2002, M. Tóth et al. 2002, Zachar and M. Tóth 2004, M. Tóth and Zachar 2006, Zachar et al. 2007) nevertheless pointed out that diverse rock types tend to serve significantly different fracture characteristics and so reservoir behavior. That is why understanding the lithological framework in each single fractured hydrocarbon field is crucial and needs a detailed study of petrology and microstructures of the given rock types.

In the Kiskunhalas (KIHA)-NE field 69 wells penetrated the metamorphic basement, but only specific segments of a few of them produce any fluid; water, oil or gas. Depth of the oil-water boundary is also significantly different in neighboring wells suggesting a highly compartmentalized reservoir. Previous studies (Cserepesné 1980, T. Kovács 1984, Árkai 1991) suggest many different rock types in the KIHA-NE field that may own various petrophysical behaviors giving a possible explanation for coexistence of permeable and impermeable zones inside the metamorphic rock body.

The aim of the present study is to characterize and classify the basement rocks of the almost unknown KIHA-NE field. Furthermore, we aim giving a thorough petrologic characterization of the most important rock types from the research area, sketching physical conditions of their metamorphic evolutions as well as outlining the spatial relationship of the main lithologies. Such a petrologic background may serve a firm

basis for modeling petrophysical properties of the complex rock body at reservoir scale in the future.

### **Geological setting**

Inside the Alpine-Carpathian-Dinaric orogenic belt the Pannonian Basin has a structurally rather complex crystalline basement, because of its complicated, multistage tectonic evolution. The essentially unknown Variscan tectonic events were followed by large scale extension during the early Jurassic and nappe formation in Cretaceous ages. Finally, the basement rocks deformed intensely due to basin subsidence during the Miocene, Pliocene ages. As a result, at present the basement is a complicated mosaic of blocks with incompatible metamorphic and structural evolutions.

The KIHA-NE field is situated south of the Mid-Hungarian tectonic zone that separates the Tisza Unit from the Alcapa Unit (Csontos and Nagymarosi, 1998). According to recent interpretations, the study area is located rather close to the assumed front of the Codru nappe, which was formed due to Cretaceous tectonic activity. Although, the KIHA-NE area has never been studied in detail petrologically, there are better known neighbouring metamorphic domes. Information concerning the petrologically well-known Jánoshalma High (JH) to the SW (Zachar and M. Tóth 2004, Zachar et al. 2007) and the Tázlár (T) area to the NE may be used for comparing results of the whole, relatively small region of the metamorphic basement (Fig. 1).

According to Zachar and M. Tóth (2004) JH is a uniform orthogneiss block with presence of numerous amphibolite and eclogite enclaves of diverse metamorphic evolutions. Zachar et al. (2007) consider that these enclaves in fact are various xenoliths of the original igneous (granitoid) body and represent rock pieces of the *mélange* zone of an ancient subduction-accretionary complex. The gneiss body itself exhibits a clear

two-phase evolution. Conditions of the first detectable, probably igneous event can only be estimated in a rather wide window of  $T \sim 700\text{--}850\text{ }^{\circ}\text{C}$  and  $P < 0.65\text{ GPa}$ . The second phase of the history is characterized by development of the schistosity at  $T < 580\text{ }^{\circ}\text{C}$ . Due to post-metamorphic ductile deformation, mylonite formed along the retrograde phase under greenschist facies conditions. Brittle deformation and widespread metasomatic overprint further complicated the current structure of the gneiss body. The most common mafic xenoliths are amphibolites and occurrence of amphibole xenocrysts in the orthogneiss texture is common too. The only eclogite xenolith is characterized by  $T \sim 710 \pm 10\text{ }^{\circ}\text{C}$  and  $P \sim 2.6 \pm 0.75\text{ GPa}$  peak followed by retrogression during decompression (Zachar et al. 2007). The original granitoid intrusion indicates a peraluminous composition and syn-collision origin (Zachar and M. Tóth, 2004).

According to the small number of previous papers dealt with the KIHA-NE field, gneiss, micaschist, amphibolite, different mylonites types, migmatite, and a low-grade phyllite variety predominate in the study area with unknown structural arrangement (Cserepesné 1980; Cserepes-Meszéna 1986, T. Kovács 1984). T. Kovács (1973) suggests that in relation to the general amphibolite facies metamorphism of Variscan age, at places migmatites and diatexites formed. In the course of the following retrograde metamorphism mylonite, chlorite schist and sericite schist evolved (Árkai, 1991). Árkai (1978, 1991) suggests that the protolith of the phyllites was a marly sediment formed under reductive conditions. Using illite crystallinity indices it underwent a very low-grade metamorphism with a peak of about  $270\text{--}300\text{ }^{\circ}\text{C}$  (Árkai, in Cserepes-Meszéna 1986). Árkai (1991) supposes that the very low-grade phyllite represents an exotic nappe, and consequently its contact to other rock types must be tectonic. Geochemical data infer weathering of the phyllite body under surface conditions.

The Tázlár field belongs morphologically to the same ridge as KIHA-NE with highly similar rock types. It, nevertheless, has not been studied in detail yet. Gneiss and various mylonite types are common with subordinate amount of graphitic carbonate phyllite and relatively fresh amphibolites. Migmatite and related lithologies are not reported in this area (Cserepesné 1980).

## **Methods**

In general, the crystalline formations of the Pannonian Basin are deep-seated and are covered by a few thousands of meters of Miocene and Pliocene sediments. The metamorphic basement can be investigated only by borecores and diverse geophysical methods. In the KIHA-NE region 69 not oriented wells penetrated the basement, among them only 25 sampled it at different depth intervals, while core recovery was only a few per cent in case of each well. At present, core samples of 15 wells are available for petrographic study, while several samples have disappeared in the last decades, and are represented only by ancient thin sections. Altogether, more than 100 thin sections were investigated, most of which belong to the collection of the Hungarian Gas and Oil Company (MOL Plc.). In order to make lithological classification in the study area as detailed as possible, petrographic investigation of each single core sample was fulfilled. Afterwards, microstructural, thermometric examinations were taken on selected samples.

### *Carbonaceous material thermometer by Raman microspectroscopy*

During diagenesis and metamorphism of sedimentary rocks the included carbonaceous material (CM) undergoes transformation from disordered CM to fully ordered graphite (graphitization). The degree of organization of metamorphic CM

indicates metamorphic grade, especially the role of temperature. The Raman spectra of metamorphic CM exhibit a significant evolution with metamorphic grade (e.g. Wopenka and Pasteris 1993, Yui et al. 1996). The process of graphitization has a strictly irreversible character; and therefore it primarily depends on the maximum temperature reached along a given  $P$ - $T$  path (e.g. Beyssac et al. 2002, Beyssac et al. 2004, Wiederkehr et al. 2011, Aoya et al. 2010). Therefore the CM structure is insensitive to retrograde metamorphic overprint or polymetamorphic evolution (Wiederkehr et al. 2011, Beyssac et al. 2002, Wopenka and Pasteris 1993). Because of the high spatial resolution and the short acquisition time, which allows numerous spectra to be recorded and therefore to quantify the sample heterogeneity, the Raman spectroscopy appears the most appropriate tool to characterize metamorphic CM. Further advantage of the method is that it can be obtained on conventional petrographic thin sections, which is a non-destructive, in situ measurement and thus the textural relationship of the CM in the surrounding matrix can be checked. The thin section has a better heat removal because of the mineral matrix and it is possible to control the orientation of CM with respect to the incident laser beam (Beyssac et al., 2002).

A Raman spectrum of CM is composed of first order (1100-1800  $\text{cm}^{-1}$ ) and second order (2500-3100  $\text{cm}^{-1}$ ) regions (Tunistra and Koenig 1970, Nemanich and Solin, 1979). In the first-order region at 1580  $\text{cm}^{-1}$  the G band (as graphite band) occurs, and three additional bands (the so-called defect bands), D1 (1350  $\text{cm}^{-1}$ ), D2 (1620  $\text{cm}^{-1}$ ) and D3 (1500  $\text{cm}^{-1}$ ) are directly related to the degree of structural disorder (e.g. Tunistra and Koenig 1970). With increasing metamorphic grade the defect bands become narrower and decreasing, while the G band becomes more intense. The second-order region is characterized by two further bands, S1 (2700  $\text{cm}^{-1}$ ) and S2 (2900  $\text{cm}^{-1}$ ); they also disappear gradually with increasing metamorphic grade.

Each spectrum can be characterized with the peak intensity ratio ( $R1=D1/G$ ) and the peak area ratio ( $R2=D1/(G+D1+D2)$ ). The more ordered graphite, the lower value of  $R2$  is characterized by. Beyssac et al. (2002) described an empirical equation to estimate the peak metamorphic temperature on the basis the parameters of Raman spectra of metamorphic CM:

$$T (^{\circ}\text{C}) = -445 (R2) + 641. \quad (1)$$

The peak temperature can be determined to  $\pm 50^{\circ}\text{C}$  due to the uncertainty on the calibration, in the range of  $330\text{--}650^{\circ}\text{C}$ . Rahl et al. (2005) modified the thermometer, applicable from  $100$  up to  $700^{\circ}\text{C}$  so that:

$$T (^{\circ}\text{C}) = 737,3 + 320,9 (R1) - 1067 (R2) - 80,638 (R1)^2. \quad (2)$$

Ayora et al. (2010) re-calibrated the geothermometer of Beyssac et al. (2002) for regional metamorphism, and found that the co-variation between  $R2$  and  $T$  can be described by the following quadratic equation:

$$T (^{\circ}\text{C}) = 91,4(R2)^2 - 556,3(R2) + 676,3. \quad (3)$$

On the basis of abundant measurements (Wiederkehr et al. 2011) methods of Beyssac et al. (2002) and Rahl et al. (2005) provide similar temperatures estimates, discrepancies being less than  $30^{\circ}\text{C}$ . Wiederkehr et al. (2011) recognized that the relative uncertainties in temperatures derived with calibration of Rahl et al. (2005) are higher compared to result with Beyssac et al. (2002), especially at temperatures above  $480^{\circ}\text{C}$ . Discussion of calibration possibilities to lower temperatures ( $\sim 200\text{--}300^{\circ}\text{C}$ ) is given in Lahfid et al. (2010).

The measurements were carried out on oriented (perpendicular to the foliation) thin sections with a THERMO DXR Raman microscope, at the Department of Mineralogy, Geochemistry and Petrology, University of Szeged, with green laser source ( $532\text{ nm}$  laser, Nd-YAG). The laser passed through an optical microscope (Olympus BX41); for

measurement the 100x objective was used in confocal mode. Irradiation power of 5 mW at the sample surface was used. The spectra were measured by high resolution grating with spectral window of 50-1861  $\text{cm}^{-1}$ , with a CCD detector. A minimum of 10 independent points were analyzed on each sample and the data were collected 20x10 s length, with quadratic fluorescent correction (following suggestions of Beyssac et al. 2002, Rahl et al. 2005).

The peak position, band area and band weight (FWHM) were determined using the computer program Peak Fit 4.12 with Voight-functions (combined Gaussian and Lorentzian profiles) after Beyssac et al. (2003).

#### *Sutured quartz grains as a deformation-related thermometer*

In metamorphic and igneous rocks complex interfingering (sutures) may occur along the monomineralic quartz-quartz grain boundaries. In numerous naturally deformed rocks Masuda and Fujimura (1981) and Hirth and Tullis (1992) studied the relationship between temperature, strain rate and the grain boundary geometry and found that the length of the suture segment increases with the decreasing temperature. Kruhl and Nega (1996) established on natural samples derived from different metamorphic grade (low-greenschist to medium granulite facies) that the sutured quartz grain boundaries are statistically self-similar and so can be represented as fractal like objects. On the calibrated geothermometer a linear function is suggested between the fractal dimension of the sutured quartz grain boundaries and the formation temperature. Kruhl and Nega (1996) also suggest that the result of the thermometer does not depend on the strain rate. This textural thermometer was refined by Takahashi et al. (1998) using artificial samples. The result of the thermometer is valid for an approximately 100 °C temperature interval. Among many others, Majumder and Mamtani (2009) used the

thermometer on deformed granite samples successfully to determine tectonic relationship and deformation history of the given rock unit.

For measurements of grain boundaries normal microscopic thin sections (30  $\mu\text{m}$ ) with identical magnification (10x) were evaluated. The sutured grain boundaries were digitalized manually. The fractal dimension values (D) were obtained by Benoit 1.0 fractal geometry software using the divider method (Mandelbrot, 1967) following the suggestions of Kruhl and Nega (1996). Slope of the regression line fitted onto the middle section of the log-log transformed L-r diagram defines D for each individual suture.

## **Petrography**

### *Orthogneiss*

Slightly foliated, coarse-grained biotite dominated gneiss is representative for the KIHA-NE field (Fig. 2/a). The principal phases are K-feldspar, plagioclase, quartz and two micas, the accessories are apatite and zircon; they usually occur as idiomorphic grains.

In all studied samples feldspar predominates over quartz (Fig. 2/b). The grains are not deformed, they are commonly sericitized and altered to carbonate and an undetermined set of clay minerals. Several feldspar grains contain quartz inclusions forming myrmekitic microtexture. The second main rock-forming mineral, quartz, shows marks of moderate ductile deformation exhibiting subgrains and slightly serrated grain boundaries. Biotite and muscovite coexist in the samples with a clear dominance of biotite what determines the foliation planes of the samples at macroscopic scale (Fig. 2/b). The large biotite flakes are reddish brown, usually fresh, although in some cases slightly chloritized. Chlorite commonly forms pseudomorphs after single amphibole

grains as well. These grains have a greenish-colorless pleochroism and bright blue, locally yellowish interference color. Small, secondary opaque and carbonate minerals are present in them as inclusions.

The fractures of the gneiss samples are usually narrow, they contain carbonate infill and in some cases have a few cm wide altered zone around (Fig. 2/a), where biotite is replaced by chlorite, while feldspar is sericitized.

### *Amphibolite*

Just a few samples represent this rock type; all of them show slightly oriented (nematoblastic) texture. Samples are strongly altered (Fig. 2/c); the chloritized amphibole grains with carbonate patches are resorbed and not oriented. The sericitized plagioclase feldspar grains form polysynthetic twins. Accessories are zircon, apatite, magnetite and ilmenite. Narrow quartz veins cut the fine-grained dark greenish samples.

### *Mica-poor granite*

The few coarse-grained granite samples exhibit equigranular texture with only moderate deformation but without any visible orientation (Fig. 2/d). These samples are of rather simple mineralogy consisting mainly of quartz, K-feldspar with a little bit of muscovite.

### *Orthogneiss mylonite*

The samples (Fig. 2/e) are characterized by biotite and nearly equal amount of feldspar and quartz with a texture reminding to that of a typical orthogneiss (Fig. 2/f). Accessories are rutile, apatite and zircon. The strongly sericitized feldspar grains are in some cases myrmekitic. The rock type exhibits mylonitic foliation (Fig. 2/g), the S

planes are formed by chlorite flakes after biotite, while the C planes show sericite bunches in the S/C fabric. Feldspar deformed in a brittle way forming microboudinage with formation of sericite, clay and carbonate minerals in the necks of the structure. Quartz grains in the samples show evidence for ductile deformation with strongly serrate grain boundaries, undulose extinction and presence of deformation lamellae. Biotite is almost entirely replaced by chlorite. The chlorite flakes with deep purple interference color often show kink band deformation and undulose extinction. White mica flakes are folded and locally form mica fishes. Carbonate minerals are common in the matrix as secondary mineral. Apatite shows clear evidence for microfaulting presenting bookshelf structure (Fig. 2/h).

The mylonite samples are significantly more fractured than the common orthogneiss is. Nevertheless, usually there is no metasomatized zone along the veins; they are mainly filled with carbonate minerals locally enclosing fragments of the adjacent rock.

#### *Graphitic gneiss mylonite*

Texturally this lithology is a fine grained mylonite characterized by a well-developed S/C fabric (Fig. 2/j). Opposite to the orthogneiss mylonite, in this case graphite defines the S planes and sericite packets are typical along the C planes. There is no biotite in these samples; the role of feldspar is subordinate, while quartz is essential. Graphite and sulphide minerals (mainly pyrite) are present in significant amounts.

Feldspar is altered to sericite and carbonate minerals, the few larger porphyroclasts are fractured and exhibit microboudinage fabric (Fig. 2/l). Quartz commonly appears as monocrystalline ribbons and shows the same markers of ductile deformation as in the orthogneiss mylonite. Sericite, the most frequent mica phase is present in fine grained aggregates and locally form folded bunches. It coexists with graphite stripes in

interfingering texture that sporadically also contain larger muscovite flakes. Graphite usually appears in narrow bands of various widths that play a remarkable role in determination of the foliation. Pyrite grains appear both in single crystals and in large aggregates; no other sulphide minerals have been determined. In some cases they are mantled by a narrow pressure fringe of quartz (Fig. 2/k). Accessories are zircon, rutile and apatite. This latter often forms bookshelf structure similar to that observed in the orthogneiss mylonite.

Carbonate minerals are essential matrix constituents. Due to their common dissolution, cavities of a few cm in size are frequently present in the samples. A few borecores are completely brecciated and highly fractured. Veins are mainly filled by carbonate with a moderate amount of quartz. Most specimens in cavities, breccia zones as well as along the numerous fractures are oil spotted (Fig. 2/i).

#### *Graphitic carbonate phyllite*

These samples distinctively consist of chaotically folded bands of fine grained black and white material (Fig. 2/m). The dark bands are characterized by graphite with some sericite and tiny muscovite flakes. Opposite to the graphitic gneiss mylonite, graphite is an essential rock forming phase (Fig. 2/n). Graphite is present in massive, thick bands interfingering with a small amount of white mica. Carbonate minerals and subordinate amount of quartz form the white bands. Pyrite, the only sulphide mineral, is ubiquitous in this lithology (Fig. 2/o). Their grains appear in varying size from sub-millimeter up to around half a centimeter forming single idiomorphic crystals and aggregates too. Individual crystals usually are surrounded by fringes of quartz and little amount of carbonate (Fig. 2/p). The pressure fringes are face-controlled and usually are deformed

(Passchier and Trouw 2005). Specimens of this rock unit are fractured; the main vein filling mineral is carbonate with rare quartz.

### **Results of Raman spectrometry**

Representative spectra for each measured rock unit are shown in Fig. 3. The characteristic spectra of the graphitic carbonate phyllite and the graphitic gneiss mylonite samples are significantly different. The intensity of D1 of graphitic carbonate phyllite is slightly higher than that of the G band, while there in the graphitic gneiss mylonite D1 band is less intense than the G band. Furthermore, the G band of the mylonite is much narrower than that of the phyllite. The G band in both cases composes a prominent shoulder (D2) on the G band. Numerical results of the Raman spectral analyses are summarized in Table 1. based on 9-14 spectra in each studied sample. The sample heterogeneity in the graphitic carbonate phyllite lithology was found to be generally small, with the average standard deviation on R2 value of 0.03. The results for graphitic gneiss mylonite have a greater average standard deviation (0.1). Plotting the results on a histogram (Fig. 4), skewness can be observed towards the smaller R2 values.

The results of the carbonaceous material thermometry are presented in the Table 1. The average difference between the result of Equation 1 (Beyssac et al., 2002) and Equation 2 (Rahl et al. 2005) is about 25 °C. The temperature values for the graphitic carbonate phyllite (n=60) with the different calibrations are  $368.1 \pm 15$  °C (Beyssac et al., 2002),  $384.2 \pm 38$  °C (Rahl et al. 2005) and  $369.8 \pm 15$  °C (Ayoa et al., 2010), while for the graphitic gneiss mylonite (n=55) they are higher, being  $411.9 \pm 45$  °C (Beyssac et al., 2002),  $387.5 \pm 35$  °C (Rahl et al. 2005) and  $415.6 \pm 47$  °C (Ayoa et al., 2010). The Student's t-test, the statistical probe regularly used to compare means of independent

populations, confirms that at a 0.01 significance level the estimated metamorphic peak temperatures for the two units are different.

### **Results of sutured quartz grains geothermometry**

This geothermometer was used in cases of the orthogneiss mylonite and the graphitic gneiss mylonite in order to provide information about temperature conditions of the ductile deformation event. The D value of the sutured quartz grain boundaries was found to be  $1.21 \pm 0.02$  (15 cases) in the orthogneiss mylonite samples, while in the graphitic gneiss mylonite samples  $D = 1.23 \pm 0.05$  (5 cases) is typical. Using the calibration scheme of Kruhl & Nega (1996) deformation temperatures of  $T_{def} \sim 470$  °C can be estimated for the orthogneiss mylonite and  $T_{def} \sim 440$  °C for graphitic gneiss mylonite, respectively (Fig. 5.).

### **Discussion and conclusions**

#### *Interpretation of the results of Raman spectrometry and the CM thermometer*

The Raman spectroscopy of carbonaceous material thermometer is quite a novel method to estimate characteristic temperature for CM containing rocks. Several factors that may influence the measurement and the temperature estimation were previously discussed by numerous papers. Hereafter the most essential points are collected. Measurement on polished surfaces may cause anomalously high D band. To avoid this effect measurement should be carried out beneath the surface, or on transparent adjacent grains (Beyssac et al. 2003). According to Beyssac et al. (2003), sample orientation may affect the Raman spectrum, especially in the case of well-crystallized graphite. Therefore it is worth measuring on thin sections oriented perpendicular to the foliation. In this way the optical axis of the laser beam set perpendicular to the mean CM axis.

Ayoa et al. (2010) investigated the orientation effect in almost deformation free contact metamorphosed and deformed regional metamorphosed samples. The measurements were carried out both perpendicular and parallel to the graphite c axis. The result in R2 values shows as little as 0.004 difference (Ayoa et al. 2010: fig 9.), suggesting that the Raman spectroscopy method can be used as a CM thermometer regardless of crystallographic orientation of CM. Furthermore, for samples nearly free from orientation R2 values depend on the sample heterogeneity, if a sufficient number of measurements is carried out (Ayoa et al. 2010).

The basic measurement parameters, acquisition time and magnification (50x vs. 100x) have no significant effect on the temperature determination (Ayoa et al. 2010). It is proved that if the wavelength (514.5 nm vs. 532 nm) and the laser energy increase, the D1 intensity decrease compared to that of G. This systematic difference, nevertheless, is negligible in temperature estimation (Ayoa et al. 2010).

Since the thermometer is based on the structural defects of the metamorphic CM, the effect of pressure or mechanical shearing have to be discussed as well. After Beyssac et al. (2004) mechanical shearing could be an important source of uncertainty, but based on their results this effect does not contribute more than a few °C uncertainties on the estimated temperature. Ayoa et al. (2010) also studied the effect of high differential stress. They consider that the deformed metamorphic CM has higher R2 values because of the more crystal defects. According to Kwiecinska et al. (2010) pressure can has a distinct influence on the process of physical-structural graphitization. Nevertheless, they emphasize the reliability of the thermometer calibrated by Beyssac et al. (2002).

Beyond these factors the CM has a natural heterogeneity (Wiederkehr et al. 2011) may have an influence on the results of the measurement and temperature estimation. During deposition CM types of various organic precursors that underwent

heterogeneous graphitization may mix (Wiederkehr et al. 2011, Rantitsch et al. 2004). Ayoa et al. (2010) note, that graphitization is a time dependent process before the attainment of the thermal equilibrium, resulting in larger R2 values of the CM. Heterogeneity may also appear within a single grain (Ayoa et al. 2010). Nevertheless, standard parameters, mean and standard deviation usually provide reliable characteristic of the data distribution (Rantitsch et al. 2004); when applying the CM thermometer the average R2 value for the sample needs to be determined (Ayoa et al. 2010). To get a reliable metamorphic temperature a substantial number of measurements might be used for each sample (Ayoa et al. 2010).

Wiederkehr et al. (2011: Fig. 9) compared Raman spectroscopy of CM derived temperatures with literature data and established that these temperatures consistently are in coincidence with the peak temperature of the given rock unit. Wiederkehr et al. (2011: Figure 5) studied in detail the relationship between calibrations of Beyssac et al. (2002) and Rahl et al. (2005). The differences in general are inside  $\pm 50$  °C uncertainty, while the relative errors of the temperature data computed by Rahl et al. (2005) are higher compared to Beyssac et al. (2002), especially for temperatures above 480 °C.

In the measured KIHA-NE samples co-variation of temperature data estimated by the two calibration methods fits well to that observed by Wiederkehr et al. (2011). Temperatures estimated by Ayoa et al. (2010) essentially overlap with those derived from Beyssac et al. (2002). In the case of the graphitic carbonate phyllite unit heterogeneity of the CM is quite small; average standard deviation for R2 value is as low as 0.03. This may indicate a uniform CM formed at  $T \sim 370 \pm 15$  °C peak temperature. Behaviour of graphitic gneiss mylonite is just the opposite. Here R2 values show significantly larger average standard deviation (0.1). In addition, its distribution function (fig. 4.) is asymmetric and exhibits a clear skewness towards smaller R2

values. If this high sample heterogeneity were caused by the above mentioned factors usually increase heterogeneity (deformation, imperfect graphitization), the data would shift towards the higher R2 values (smaller temperatures). That is why it is suggested that the above effects are not responsible for the observed heterogeneity. Instead, in the mylonite zone rock fragments of diverse metamorphic histories may have got juxtaposed. Although, the most typical rock type is characterized by  $T \sim 410\text{ }^{\circ}\text{C}$ , some pieces probably represent even higher temperature. In the graphitic gneiss mylonite Raman spectrometry data indicate mixing of rocks of different peak metamorphic conditions along the one time shear zone.

#### *Petrological interpretation*

According to the results of the petrologic and thermometric study, the KIHA-NE field consists of four main lithological units with incompatible structural and metamorphic evolutions. Each well that samples more lithologies suggests the same systematic spatial order for the four block along the ideal rock column with orthogneiss, orthogneiss mylonite, graphitic gneiss mylonite and graphitic carbonate phyllite from the bottom to the top (Fig. 6). The figure displays a summary of the thermometric results for the four units outlined above.

Gneiss samples in the lowermost structural position are similar in all mineralogical and textural characteristics to those described by Zachar and M. Tóth (2004) for the JH dome. Based on presence of relic myrmekite as well as euhedral habit of the accessory phases (zircon, apatite) the protolith of this gneiss variety is of igneous origin. Similarly to the JH area, sporadic appearance of amphibole xenocrysts in the gneiss matrix is typical. There are only a few amphibolite samples available in the KIHA-NE area. They all appear inside the orthogneiss dominated interval, so even if amphibolite pieces do

not exhibit a clear evidence for the contact with the gneiss, they should be xenoliths in the orthogneiss body similar to the adjacent JH dome (Zachar and M. Tóth, 2004). Presence of the mica-poor granite specimens further strengthens similarity between the two neighbouring localities.

The gneiss mylonite samples have a highly similar mineral assemblage and relic textural features to the lowermost orthogneiss body suggesting that orthogneiss should have been the protolith of the gneiss mylonite and their evolution had to be identical prior to the last ductile deformation event. The typical deformation features, presence of mica fish, bookshelf texture as well as microboudinage all indicate mylonitic deformation in an extensional rather than compressive stress field (Passchier and Trouw, 2005). According to the retrograde mineral assemblage (sericite, chlorite, carbonate minerals), the ductile deformation took place under low grade conditions. The quantitative determination of the temperature of mylonitization gives  $T_{def} \sim 470$  °C with significant but poorly estimated error due to the rough calibration method and the uncertainty of image analysis.

The graphitic gneiss mylonite, on the basis of its mineral composition can clearly be separated from both the orthogneiss and the graphitic carbonate phyllite. Its undeformed protolith is still unknown from the adjacent terrains of the basement. The carbonaceous material thermometer allows to estimate the peak metamorphic temperature of this rock type with  $T \sim 410 \pm 45$  °C. Mylonitic deformation of this rock unit can be characterized by extensional textural features at  $T_{def} \sim 440$  °C.

According to Árkai (1991) the graphitic carbonate phyllite probably had a marly protolith formed under euxin facies conditions. Although mineral assemblages of the two upper lithological units are similar, the evidently different Raman spectra of the carbonaceous materials of the graphitic carbonate phyllite and the graphitic gneiss

mylonite samples prove their distinct evolution. Furthermore, carbonaceous material is more homogeneous in case of the graphitic carbonate phyllite unit resulting in temperature estimations of much lower peak temperature with smaller uncertainty ( $370\pm15$  °C).

#### *PTd evolution*

Borecore data of several wells suggest that at the deepest structural position of the ideal rock column an orthogneiss is common in KIHA-NE field. Based on textural features this rock type might be identical to that described in detail by Zachar and M. Tóth (2004) and Zachar et al. (2007). The existence of a SW-NE extended orthogneiss zone in the southern part of the Pannonian Basin has already been assumed by Szepesházy (1962) who found that JH block is the westernmost part of this belt. Assuming the identity of the neighboring orthogneiss blocks, the metamorphic conditions of JH gneiss ( $T < 580$  °C, Zachar and M. Tóth, 2004) can be applied for KIHA-NE block too.

Although, besides the orthogneiss samples also a highly mylonitized variety is known from the KIHA-NE area, the transition between the two lithologies is not exposed. In the JH block only a few samples remind to the effect of the post-metamorphic greenschist facies mylonitization event (Zachar and M. Tóth, 2004) without any information about the spatial context. A much better represented situation is reported from the Szeghalom-N area (NE from the KIHA-NE field) by Schubert and M. Tóth (2002). Here wells penetrated and sampled an almost 150 m thick shear zone from the undeformed orthogneiss down to the mylonitic core zone and proved a continuous change. In spite of missing transitional rock types between orthogneiss and mylonite, a similar situation is assumed for the KIHA-NE area. In the Szeghalom-N field mylonitic

deformation temperature of  $T_{def} \sim 430$  °C was calculated in orthogneiss using the quartz suture thermometer (János et al., 2007). A rather similar value can be estimated for the KIHA-NE orthogneiss mylonite samples suggesting comparable post-metamorphic evolution.

Although metamorphic evolution of the next block upwards along the KIHA-NE ideal rock column is essentially different, mylonitic deformation temperature of graphitic gneiss mylonite is comparable to that calculated for the orthogneiss mylonite. These  $T_{def}$  values are also coherent with the textural observation that in both sample groups feldspar deforms in a brittle way (Voll, 1980).

The two uppermost lithological blocks consist of similar, but slightly different mineralogical compositions. Calculated metamorphic peak temperatures are also different, but have a slight overlap.

All thermometry data together suggest that the present lithological section exposed in the upper few hundred meters of the KIHA-NE area does not represent an undisturbed piece of the original Variscan lithosphere. Rather the total thickness of the missing portion is significant. In fact, between the top and the bottom of the ideal rock column there is about 200 °C peak metamorphic temperature deviation. Depending on the local thermal gradient this may mean even reach 5-10 km total difference in formation depth. The metamorphic peak temperature of the graphitic carbonate phyllite is the lowest; it must represent the shallowest portion of the one-time lithosphere. After a several hundred meter thick hiatus the undeformed variety of graphitic gneiss mylonite follows downward. The position of the orthogneiss block in the original metamorphic column was several km deeper. This picture necessarily implies presence of post-metamorphic tectonic boundaries between the subsequent lithological units.

Taking the uncertainty of the applied thermometry methods into account, the estimations of peak metamorphic temperature and that calculated for deformation overlap significantly suggesting mylonitization happened close to the deepest point of the metamorphic evolution of the graphitic gneiss mylonite. This value furthermore is identical to that calculated for mylonitization of the orthogneiss block. So, both the textural features implying deformation in extensional regime and the estimated temperatures (~455 °C) are rather similar for the two mylonitic lithologies. This suggests that although physical conditions of the peak metamorphism were significantly different, the last deformation events of the two bodies are in close relationship. The two contrasting metamorphic blocks got juxtaposed along an extensional fault zone in the basement at approximately 15 km depth (Fig. 7.). We suppose that the same event may have been responsible for transportation the graphitic carbonate phyllite on the top of the graphitic gneiss unit. As a result of the large scale motion several km thick material has disappeared due to tectonic erosion.

Appearance of blocks of contrasting metamorphic evolution in a relatively small region is not uncommon in the basement of the Pannonian Basin. A similar situation has been inferred in the Mezősas-Furta, Szeghalom and Dorozsma areas previously (M. Tóth and Zachar, 2006; Schubert and M. Tóth, 2002; M. Tóth and Zachar, 2002; M. Tóth et al., 2002). The age of this tectonic event essential for a significant part of the metamorphic basement is still unknown. Following the mylonitization the whole basement block consolidated, uplifted and probably were exhumed to the surface as it is indicated by surface weathering of the graphitic carbonate phyllite proved by Árkai (1991).

## **Acknowledgement**

We thank MOL Hungarian Oil and Gas Company for making the study of the samples and thin sections possible. Balázs Kiss is thanked for the fruitful discussions about the behavior of the KIHA-NE reservoir. Kálmán Török is thanked for a thorough review and constructive criticism. The procurement of the THERMO DXR Raman microscope was financially supported by the Gábor Baross Program (Baross – DA07-DA-ESZK-07-2008-0007).
